The sigmoid flexure has, as we expected, a variable length and size. In normal cases it is situated well within the pelvic brim and does not pass much to the right of the median line. The length of abnormally long sigmoids may be estimated by the distance to the right of the median line and the height to which they extend. In three of our cases the shadows of the sigmoid and cecum impinge. In two of the cases long and dilated sigmoids are present, associated with colons of normal length. In one of our patients the sigmoid and rectum held the bismuth for over seventy-five hours and it was forty-eight hours more before the patient passed bismuth in the stool. This made a total residence of the feces in this part of the intestinal tract of over five days. The patient had a long-standing constipation, followed by hemorrhoids, which were excised. The radiographs show a long, looped and ptosed colon, with a long and tortuous sigmoid and upper portion of the rectum.

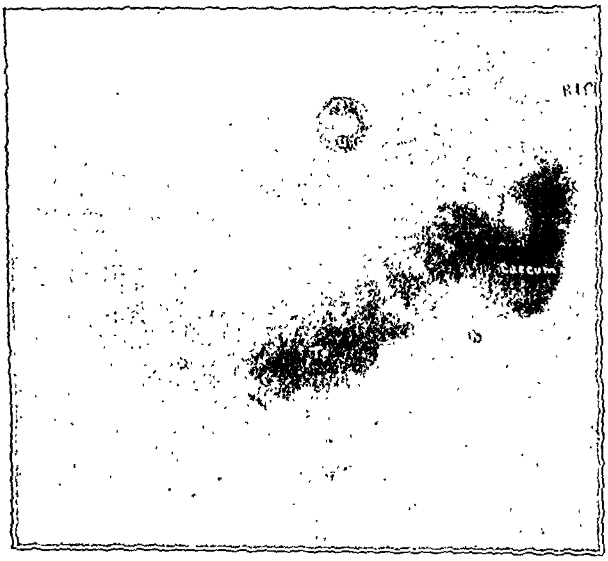

Fig. 3.—Radiograph taken twenty-six hours after the ingestion of a bismuth meal (Case 1). T, *transverse colon*, now become U-shaped; A, vermiform appendix, bent on itself; F, *traces of bismuth* in the sigmoid flexure; C, ascending colon. The lighter areas in the upper part of the colon are due to gas formation.

Our treatment for these cases of gastroptosis, enteroptosis and coloptosis consists of an abdominal wall support, often reinforced by two horsehair pads arranged ventrally, so as to support the colon. Goldthwaite's posture[15] taken immediately after eating, with the patient on his back, hips and thighs elevated, has been tried successfully in a number of cases.

CASE REPORTS

Case 1.—M. McD., a woman aged 27, child's nurse, single, ever since childhood had been constipated and had to take cathartics or laxatives. For the past two years she had been getting worse, vomiting having occurred from one-quarter to one-half hour after meals. She had pain, which was most marked in the epigastrium, but which also at times extended lower down on the right side of the abdomen and into the right hip and leg. Distress and soreness after eating were invariably present over the sternum. During the summer and fall of 1910 she developed hemorrhoids, which became inflamed and were removed in January, 1911.

After the operation, the patient's symptoms continued; the obstinate constipation could not be relieved by medical means, the chief of which were olive oil internally, ordinary enemas, and olive oil per rectum, colon massage, and vibration. Analysis of the gastric contents showed traces of free hydrochloric acid. The stools were very dry, hard and contained undigested food.

In May, 1911, the bismuth-Röntgen-ray test was made. This showed a stomach of normal shape and size, but ptosed, with a complete emptying in three hours. The bismuth reached the cecum in two hours, and the small intestine was completely emptied in five and one-half hours. Four hours after the ingestion of the bismuth, the cecum and part of the transverse colon were filled, the transverse colon straight, and the hepatic flexure 2 inches above the umbilicus, and therefore no ptosis apparent. The shadow of the bismuth in the ascending colon was so heavy that in consideration of the next picture the colon seemed to be folded on itself (Fig. 2.) One hour later the bismuth meal had not made any progress, but the apparent churning motion and the weight of the residue had dragged down what must have been a folded colon, and distended the appendix. This organ could be plainly outlined by the bismuth in the lumen; it overhung the brim of the true pelvis, was long, and made a sharp bend near its middle. In the last plate of the series, taken 101 hours after the bismuth meal, the outline of the bismuth in the appendix could still be plainly seen. Four hours later, or nine hours after the ingestion of the bismuth, a most remarkable drop in the transverse colon occurred, making a large central loop reaching down into the true pelvis, and the hepatic flexure was one inch lower than in the previous picture (Fig. 3). Twenty-six hours after the bismuth had been taken, very little progress had been made, but the whole colon was distended with gas which collected in the upper parts and raised apparently the level of the hepatic flexure. The sigmoid flexure was outlined in places, and the colon retained the same shape as before. The eighth plate of this series, taken forty-eight hours after the bismuth meal, showed very little progress in the looped colon. The bismuth did not show in the descending colon, but filled fairly well the sigmoid flexure. Up to this time the patient had had no bowel movement; seventy-seven hours after the bismuth meal, the colon retained its same position, but the main mass of the bismuth was still in the sigmoid flexure and the rectum. The sigmoid was very tortuous and long. The appendix was in the same position as before, and the same size. At the one hundred and first hour, without a movement, the bismuth was massed in the sigmoid and rectum and the appendix was still full of bismuth. It was two days after this picture was taken before the bismuth appeared in the stool, making a total of six days for the bismuth to pass through the gastro-intestinal tract. The diagnosis made in her case was a very severe case of constipation which, from the history, was probably the causative factor of the ptosed colon. At the time of writing, a laparotomy, with appendectomy and colopexy, is being considered.

---

[15] Goldthwaite, J. E.: Boston Med. and Surg. Jour., May 19, 1910.

CASE 2.—B. S., a girl 18 years old, shirt-waist maker, said that her mother had an ulcer of the stomach. For years the patient had had obstinate constipation and three years before she had been operated on for appendicitis and abscess formation. Since that operation the constipation had been growing worse, with headache across the temple, cramplike pains in the abdomen, worse at night, vertigo, heartburn, nausea, and occasional attacks of syncope which compelled her to give up work. She had no appetite and would vomit small amounts of food after eating; she said that she had vomited a tablespoonful of bright blood two weeks before examination by us in February, 1911. Her diet had been reduced to a ridiculously low amount, with nothing before lunch time. She had lost weight, but was still fairly well nourished. Her chief complaints were obstinate constipation, frequent vomiting, and pain in the epigastrium and back. Examination of the abdomen showed a good-sized scar over the appendiceal region, abdominal musculature was of good tone, and there was no distention. The outlines of the stomach seemed normal, but there was tenderness over the whole abdomen in general, which was localized over the epigastrium and along the spine, and more marked at the level of the tenth and eleventh dorsal vertebræ. The Ewald test meal showed a 0.07 per cent. and 0.04 per cent. free hydrochloric acid on two occasions respectively, with a total acidity within normal bounds. No lactic acid was present.

The diagnosis of an ulcer of the stomach as being the cause of her trouble seemed unlikely, no blood or occult blood being found in the gastric contents or stools. Lavage relieved her somewhat, but only temporarily. February 27, the bismuth Röntgen-ray test was applied. The first picture, taken fifteen minutes after the swallowing of the bismuth, showed a nearly normal stomach, oblique fish-hook type, which emptied rapidly. The rugæ in the cardiac end were well marked. Within five hours the organ was completely empty. The small intestine was well down in the pelvic cavity.

The last picture in this series was taken twenty-four hours after the bismuth meal, and showed a ptosed cecum and splenic flexure. All the bismuth was in the large intestine, and the transverse portion of the colon has a long U-shaped loop, the lower border of which is 4 inches below the umbilicus, with its center 2 inches to the left of the median line. As this was one of our early cases, unfortunately we did not continue the series until the gastro-intestinal tract became completely empty. For a month and a half the patient was treated by regulation of the diet, massage and vibration, olive oil by mouth and per rectum, and by the usual instructions for regularity, etc., but an occasional cathartic was the only thing that gave her relief, and that only for a day or two. The flatulence, pain and vomiting continued. The pain now seemed localized over the left kidney with tenderness there, and an x-ray picture showed absence of renal or other calculi. An exploratory laparotomy showed the long, looped and ptosed colon, which was distended with feces, in spite of previous catharsis and high enemas. One adhesion of the cecum to the abdominal wall, as the result of the appendectomy, was cut. The cecum was dilated but otherwise not pathologic.

Palpation of the stomach gave no evidence of ulcer or growth. The kidneys, gall-bladder and other organs seemed normal. The loop of the transverse colon was freely movable and low down in the pelvic cavity. With no permission to do a radical operation on the intestine, we closed the wound.

Since the operation the patient's condition has not improved, except for a short time after an abdominal web belt for the support of the ptosed colon was provided, and the patient sent to the country. At the end of last May she reported that the constipation was no better and that she still had attacks of sickness. She and her family have been advised of the probable necessity of a radical operation on the intestine, and of the dangers of the same, and have agreed to have it performed soon. We propose to sidetrack part of the colon, or possibly excise part of it.

CONCLUSIONS

1. The length of time that it takes the contents of the gastro-intestinal tract to reach each division of the tract, and the time in which the division is completely emptied, can be definitely determined in each individual by the bismuth Röntgen-ray test.

2. The normal motility of each part of the gastro-intestinal tract can be definitely established.

3. The food immediately after ingestion begins to pass into the small intestine and by the end of an hour, at least one-quarter of the gastric contents is in the jejunum.

4. The stomach is emptied of 500 c.c. of milk or soup in two and one-half to four hours.

5. The existence of an increased amount of free hydrochloric acid in the gastric contents has no influence on the final emptying time of the stomach.

6. The time which this meal consumes in passing to the cecum averages two hours, varies from one to four hours, and is shorter in children.

7. The complete emptying time of the small intestine after this meal is probably about six hours.

8. Complete emptying of the colon consumes from twenty-four to forty-eight hours.

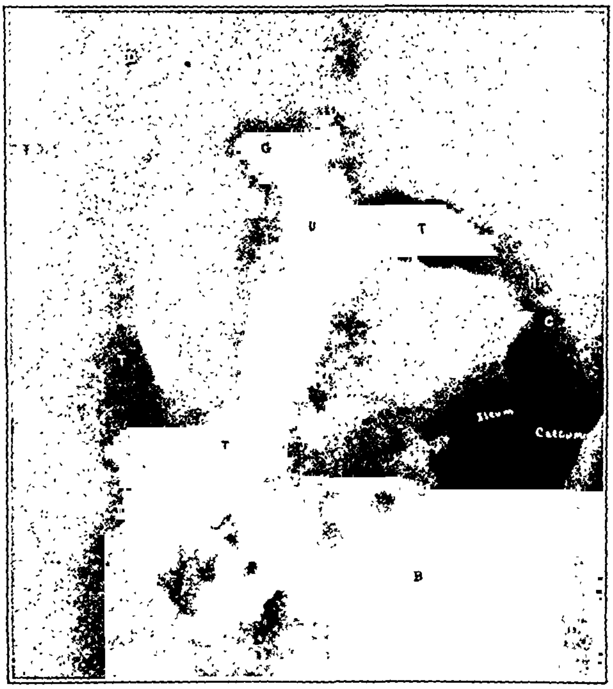

Fig. 4.—Radiograph taken three hours after the ingestion of a bismuth meal. This shows the rapid passage of food through the stomach and small intestine. The colon is dragon-shaped. H, hepatic flexure; T, transverse colon; D, splenic flexure; G, traces of bismuth in the stomach; B, bismuth in the small intestine. Case 6 [not reported in detail].

9. The bismuth-Röntgen-ray test is harmless and practical.

10. The ordinary methods of medical treatment can be more intelligently applied with the improvement in diagnosis accomplished by this test.

11. The bismuth-Röntgen-ray test should be employed before an operation is performed for a chronic condition of the gastro-intestinal tract.

We wish to thank Dr. George B. Wallace and Dr. John C. A. Gerster for their help in sending us patients, Dr. Arthur Mandel for his assistance in clinical and chemical analyses, and Dr. Alexander Smith, Dr. Egbert LeFevre and Dr. Harlow Brooks for their encouragement in undertaking the work.

CERVICAL IMPLANTATION OF THE PLACENTA WITH RUPTURE OF THE UTERUS

HYSTERECTOMY; RECOVERY

CHARLES GOODMAN, M.D.
Attending Surgeon to Beth Israel Hospital; Sydenham Hospital; Montefiore Home Chief, Surgical Department, Mt. Sinai Hospital Dispensary
NEW YORK

Any investigations which throw light on the causation or treatment of that greatest of obstetrical calamities, rupture of the uterus, are of importance to the obstetrician, the surgeon and the general practitioner. The most frequent causes of this condition are obstructions to the descent of the fetus, with neglect of the procedures necessary for delivery of the child, as in patients treated by midwives or by the laity. Such obstructions are often in the form of contracted pelves, or tumors of the pelvis encroaching on the parturient canal. A normal fetal head of large measurements or a hydrocephalic head may cause obstruction by failure to enter a normal pelvis. Malpositions of the fetus, as a transverse position with a shoulder presentation, lead invariably to obstruction unless properly cared for.

Rupture of the uterus has been the direct result of manipulations, as attempted versions or the use of the hand or curet in efforts to empty a pregnant uterus. Even external violence has been known to produce rupture. The improper administration of ergot in the early stages of labor may cause a tetanic action of the muscle of the upper uterine segment which may end in a thinning out and tearing of the lower segment.

Finally, abnormalities of the uterus itself, as pathologic changes in various portions of its walls, or deformities, as bicornate uterus with a pregnancy in one cornu, play a prominent part in the causation of uterine rupture. The presence of carcinoma, syphilis or soft myomata in the uterine walls, predisposes to its occurence. The scars of previous Cesarean sections often give way during labor and the cervix has sometimes proved so rigid or stenosed as to resist all efforts of nature to dilate it until the thinned-out lower uterine segment is torn apart by the straining efforts of the uterine muscle. Very rarely an ectopic gestation in the mural portion of the Fallopian tube, as it gradually enlarged, has put the uterine wall on the stretch until it has suddenly given way with all the signs of a ruptured ectopic pregnancy in their severest form.

I have observed a case which exemplifies a very rare cause of rupture of the uterus.

History.—The patient was 28 years old, the mother of two children, 2 and 4 years of age, respectively. The first child was delivered with forceps, while the second was the result of a normal pregnancy and delivery, with the exception that at the end of eight months the patient had a slight bloody vaginal discharge which disappeared after a few days' rest in bed. She had had two miscarriages, the last one early in July, 1910, at about seven weeks. Her last menstruation was on May 15, 1910. About the middle of August of the same year, when three months pregnant, she was shocked by the news of the sudden death of her father, and a few days later began to complain of pains in the pelvic region, with a desire to urinate frequently. She consulted a physician who made a very cursory general investigation, omitting the vaginal examination, and pronounced her case to be one of bladder inflammation, for which he continued to prescribe every few days during the subsequent two weeks. Early in September, after intercourse with her husband, she suffered severe pain in the right lower abdominal quadrant. Her physician, who was immediately summoned, gave her a hypodermic of morphin. One week later, after intercourse, she had a similar attack of severe pelvic pain in the right side, for which, as before, she was given a hypodermic. This was followed by retention of urine. She was confined to bed four days, during which time she was catheterized twice daily. For this purpose a glass catheter kept in a solution was utilized. During the following three weeks she had slight pains in the pelvis, some headache and was constipated. During this time she had no intercourse on account of the fear of bringing on another attack of severe pain. Another attempt at coitus on October 2 brought on intense abdominal pains and rectal tenesmus. The physician was called and administered a hypodermic and gave the patient an enema. After this she fell asleep for about two hours, when she was awakened by the recurrence of pain, followed by attacks of syncope. When the doctor returned, he found her in great agony with abdomen distended and a failing pulse. Believing that rupture of an ectopic pregnancy had occurred, I was summoned.

Examination.—When I saw the patient her skin and mucous membranes were completely blanched. Her abdomen was distended with fluid and her pulse had become imperceptible. Faint and fluttering heart sounds could be auscultated. She was conscious, but so weak that she could speak only in monosyllables. On digital examination, I felt the vaginal portion of the cervix somewhat enlarged and having the soft, velvety consistency of pregnancy. The os was closed and there was no sign of any discharge. The vaginal fornices and the pouch of Douglas felt boggy and were very tender to the touch. The fundus of the uterus could not be mapped out on account of the extreme distention and sensitiveness of the abdomen. A detailed examination was not deemed advisable on account of the urgency of the case.

Operation.—I agreed with the doctor in attendance that we had to deal with a probable ruptured ectopic gestation and made arrangements to have the patient transferred to the hospital. On her arrival, she was immediately taken from the ambulance to the operating table. A hypodermic injection of morphin was given and ether was administered by the drop method. On opening the peritoneum a large quantity of fluid and clotted blood was found, and a large fluctuating tumor presented which seemed to be wedged into the pelvis. When this tumor was lifted from the pelvic cavity, it proved to be a pregnant uterus with an attenuated anterior wall which at first sight was mistaken for an ovarian cyst. At the extreme left border of the anterior wall near the broad ligament there was a rent about the size of a silver quarter through which shreds of placental tissue protruded. Behind the uterus more fluid and clotted blood was found. The appendages were normal in appearance. Cesarean section was deemed inadvisable, as, from the meager history obtained during the emergency, I was not sure that there had been no interference and accompanying infection. Furthermore, the condition of the uterine wall was such as not to justify an attempt to suture it. Where the products of pregnancy were retained, the walls of the uterus were as thin and fragile as paper. Hysterectomy was therefore decided on. The bladder was separated from the anterior uterine wall, which was here so thin and paper-like that it was torn, allowing the escape of amniotic fluid, followed by the presentation of the lower extremities of the fetus at the opening. In order to facilitate the handling of the uterus, the fetus was extracted in an upward direction through this tear. The ovarian arteries were clamped and divided and the rectum separated posteriorly. The right uterine artery was then ligated, the cervix cut through and the ligature applied to the left uterine artery. In order to get below the attachment of the amniotic sac, I cut deeply into the cervix, but, although only a small portion of the cervix was left intact, I did not succeed in getting entirely beyond the confines of the placental attachment. The uterus was delivered with the placenta attached. As soon as the toilet of the peritoneum was completed, a saline solution of 1,000 c.c. was injected into the right median cephalic vein and the abdomen was closed without drainage.

Outcome.—During the first twenty-four hours after operation the patient received proctoclysis and some hypodermic stimulation. The bowels were moved by calomel and salts on the third day. Convalescence was uneventful with the exception of a slight rise of temperature due to a stitch abscess near the upper angle of the wound. The patient was discharged from the hospital at the end of three weeks. She now feels perfectly well, has gained seven pounds in weight and is able to attend to her household responsibilities. The hemoglobin, which was 30 per cent. on the day subsequent to the operation, is now 85 per cent.

Pathology.—The pelvis was carefully examined in order to ascertain whether an anomalous condition was present which might have contributed to the cause of rupture.

It is evident from the following measurements that no such anomaly existed:

Distance between the anterior superior spines, 23 cm.; intertrochanteric diameter, 30 cm.; external conjugate, 20 cm.; right and left obliques, each, 22 cm., and the internal conjugate, 11 cm.

The uterus after hardening measures 3½ by 4 by 2 inches, excluding the placental site, which is so torn and irregular as to prevent accurate measurement.*

An anterior thin wall lodging the placenta continues down from the normal thickness of the uterus. This portion when spread downward measures between 3 and 4 inches.

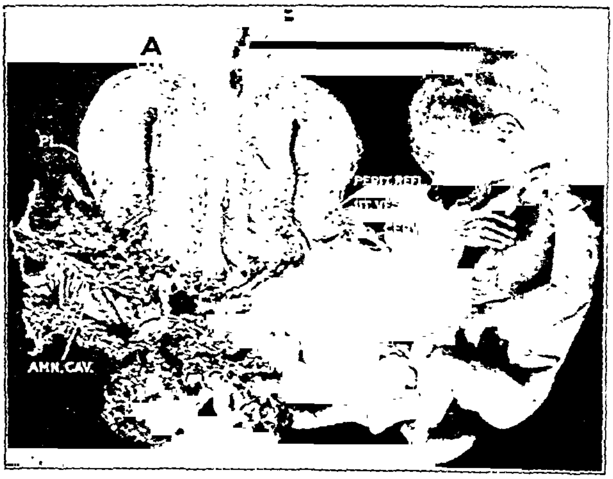
Similarly, the posterior portion of the uterus is a thin muscular wall which also gives attachment to placenta. When the flaps are restored to their natural relations, it is apparent that the placenta occupies the inner surface of the dilated lower portion of the uterus. The posterior portion of the placenta showns an amnion with the umbilical insertion still well preserved. Attached to the cord was a well-formed female fetus 9½ inches in length, nearly 5 months old.

On sagittal section of the uterus, microscopically, the placenta seems to begin at the dilated thin lowermost portion of the uterus just below the insertion of the uterine vessels and nearly corresponding to the anterior and posterior reflections of the peritoneum. This would mean that the placenta occupies the cervical portion of the uterine canal commencing at about the isthmus. The corporeal portion of the canal seems altogether devoid of placenta, microscopically.

Microscopically, the lowermost portion of the uterus shows chorionic villi lining the canal. The glands are for the most part absent. When seen they show very low cylindrical epithelium which has the tendency to form papillæ and are for the most part corpus glands. Only in the smallest areas can cervix glands be seen in sections which also show chorionic villi. These latter are of the transitional form, i. e., they contain for the most part syncytial cells, while the Langhans cells are beginning to disappear. There is an unusually large amount of lime. The chorionic villi show a moderate tendency to penetrate the cervical parenchyma. In some portions of the myometrium, however, a variable number of serotinal giant cells are seen. The musculature shows an outspoken hypertrophy. Here and there is a leukocytic infiltration. This is most marked in the thin walls of the lowest portion of the uterus, where, furthermore, the vessels are filled with thrombi. The thin portion of the uterus measures from ⅛ to ¼ of an inch as compared with 1½ inches thickness of the corporeal portion of the uterus.

While evidences of the inflammatory reaction are not sufficient in this specimen to provide a predisposing cause for spontaneous rupture, the examination proves the presence of a condition quite analogous to one of the aberrant forms of pregnancy, as in the extra-uterine or interstitial varieties. The placental site was below or at the isthmus and its development took place within the cervical canal. There was obviously not sufficient room for the ovum to expand beyond a period of five months. It impinged against the linea iliopectinea. This was a predisposing cause of rupture, the real cause being the fact that the chorionic villi had invaded the entire parenchyma of the wall of the cervix, favoring rupture, as in tubal pregnancy. This process was confined to the small pelvis and the thinned-out cervical walls finally gave way to the increased pressure. It is probable that coitus played an important traumatic rôle in the history of the case.

The mechanism of uterine rupture in this case differs materially from that involved in most cases. Bandl, in 1875, described a ring of fibers in the inner wall of the uterine muscle located about 12 to 15 cm. above the internal os at full term. This is the dividing point during labor between the upper uterine segment, which, by its contraction, propels the fetus through the parturient canal, and the lower uterine segment which is simply passive and dilates to form a passage for the fetus. In the presence of obstruction to its passage through the parturient canal, the upper segment, in its efforts to overcome the obstruction, continues to exert tension on the thinned-out lower segment until a tear occurs. Such an explanation for the rupture in my case can scarcely be taken into account, as the relations of the upper and lower uterine segments are of significance only at a full term delivery.



The photograph shows the two halves of the uterus and attached placenta: A, right half; B, left half; Ut. Vess., uterine vessels; Perit. Ref., lowermost points of peritoneal reflection; Pl., uppermost attachment of placenta; Am. Cav., amniotic cavity; Cerv., cervix.

My conclusion that the case was one of cervical implantation of the placenta is based on the following grounds:

1. The uterus is divided into two general portions, a well-preserved, thick upper portion, and a very much thinner lower portion. The placenta is attached to this lower portion. Neither macroscopically nor microscopically can evidences of placental attachment, such as retained villi, decidua or giant cells, be demonstrated in the body of the uterus.
2. The point where the placenta appears macroscopically corresponds to a line drawn between the insertion of the uterine vessels on either side, and also between the anterior and posterior peritoneal reflections. Both of these landmarks indicate the level of the isthmus and the internal os.
3. The placental attachment was demonstrated in contact with cervical glands.

The findings prove that the case was one of pregnancy at about the fifth month, with spontaneous rupture of the uterus, due to a cervical implantation of the placenta.

---

* Dr. I. C. Rubin will publish a more detailed pathologic report of the specimens of this case at a later date.

This is probably the first case of its kind reported in this country.

A careful review of the literature of the subject reveals several cases on record abroad in which placental tissue was undoubtedly attached to the cervix.

L. Müller has reviewed the literature, but without finding cases in which the anatomic investigations were thorough enough to assure the correctness of the diagnosis.

In more recent years several cases have been reported which are so convincing in their clinical and anatomic aspects that the occasional existence of a placenta prævia cervicalis cannot longer be doubted.

Dr. Otto v. Weiss[1] reported a case of a quintipara, aged 33, who was admitted at full term on account of profuse hemorrhage, with a diagnosis of placenta prævia. Tamponade was followed by podalic version and delivery, with the loss of a large amount of blood. The child died during the attempt at delivery. The placenta was found intimately adherent to the cervical mucous membrane and was separated from it with great difficulty by manual extraction. A chill and fever occurred and it was found that there was a streptococcus infection with retained shreds of placenta. Vaginal hysterectomy was followed by death on the third day.

A. Keilmann[2] reported a case of a tertipara admitted with ruptured membranes, slight labor pains and some hemorrhage. Spontaneous delivery occurred. Two hours later a portion of undelivered placenta was found adherent to the anterior lip of the cervix and was removed with great difficulty by manual separation.

E. Ponfick[3] reported a case of a nonipara with repeated hemorrhages during pregnancy. A diagnosis of placenta prævia was made and on the left and posterior aspect, the placenta was found to be continued down inseparably adherent as far as the vaginal portion of the cervix.

Jaschke[4] reports a recent case of placenta isthmica et cervicalis.

The cases which have been so far reported in the literature have not been supported by microscopic evidence and are so few in number as to warrant the assumption that placenta prævia cervicalis is either a very rare condition or one which is very rarely recognized.

969 Madison Avenue.

SUBPARIETAL RUPTURE OF SOLITARY KIDNEY *

A. J. MAYER, M.D.,† AND A. NELKEN, M.D.
NEW ORLEANS

The horseshoe kidney, while rare, is sufficiently common to require no especial comment. Those anomalous conditions in which the kidneys are completely fused into one mass are of much less common occurrence. To this condition, the *Kuchinniere* of the Germans, Rokitansky applied the term "solitary kidney," to differentiate it from the true single, or "unsymmetrical" kidney.

Morris, reviewing the statistical reports of four of the largest of the London hospitals, found that while the "horse-shoe" kidney was present once in each 1,000 autopsies, the fused kidney, not of the "horseshoe" variety, was found only once in 15,908 necropsies.

Subparietal rupture of the kidney is comparatively rare. Connell, in a paper read before the Western Surgical Association,[1] collected from all sources a total of 841 cases.

Our case of subparietal rupture of a "solitary" kidney is, we believe, unique in the literature.

History.—Our patient was a white man, 30 years of age, a native of England, and a sailor by occupation. We were unable to get a connected account of his injury and the sequelæ, but, as far as we were able to gather, seven days prior to applying for treatment, while climbing a ladder, he had fallen a distance of from four to six feet. In falling his body swung around, and he struck with his right lumbar region on an iron rail. He complained of some pain in his right side, following the injury, but continued to void urine up to seven days after the accident. We were unable to learn whether or not this urine contained blood. His urine stopping suddenly (?), the captain of his ship sent him to the Touro for treatment.

Examination.—The patient was admitted to the service of Dr. Matas who requested Dr. Mayer to look after him. On admission the patient's general condition was good, his temperature was normal. He showed considerable ecchymosis in the right lumbar region and in the perineum. A large diffuse swelling could be felt in the right side almost to the umbilicus, and longitudinally from the last rib to the pelvis. The abdomen was distended and very tense. About two ounces of bloody urine were withdrawn by catheter. He was catheterized twice more in the following twenty-four hours, but no urine was obtained. He vomited three times the day following admission.

Diagnosis.—The question of diagnosis was interesting. The history of the injury and the mass in the right side suggested at once rupture of the right kidney. But rupture of the right kidney would not explain the absence of urine in the bladder, since there was no evidence of damage to the left kidney. Rupture of the bladder, with postperitoneal infiltration of urine was contra-indicated by the nature of the injury, and, especially, by the fact that the patient had voided urine normally for seven days after the accident.

The possibility of there being but one kidney was discussed, but, if this rare anomaly was present, we could not explain why a ruptured single kidney should secrete what the patient described as being comparatively normal urine for seven days, and then suddenly cease functioning. Rupture of the right kidney, with subsequent sloughing of the bladder-wall, the reason for which we did not understand, seemed to us to be the only plausible explanation of the conditions present.

Because of this opinion, and because the condition of the patient did not justify any unnecessary delay, no attempt at cystoscopy was made. As was demonstrated by subsequent findings, cystoscopy with catheterization of the ureters would have been unintelligible or even misleading, unless styleted catheters had been used and a radiograph taken.

Operation.—At Dr. Matas' suggestion, an exploratory laparotomy was done. The incision was made to the left of the median line, to avoid possible contamination of the peritoneal cavity with what appeared to be infiltrated urine beneath the abdominal wall on the right side. When the peritoneum was opened, the cavity was found to contain about a pint of clear fluid which had no urinary odor. To the right, postperitoneal, extending from the last rib to the crest of the ilium was a large oval swelling which evidently included the right kidney. No left kidney could be found, although search was made as high as the spleen and as low as the pelvis. The bladder was tested and found to be intact. The abdominal wound was closed with some difficulty because of the intestinal distention and the patient turned over on his left side. The ordinary loin incision was made over the right kidney. As the muscles were being cut through there was a gush of bloody urine. The wound was enlarged and the hand introduced. The kidney was found to be lying slightly lower than usual, but otherwise its position was normal. The lower pole of the kidney was roughly broken off and sloughing. The cavity below the kidney was filled with what seemed to be sloughing tissue and partially organized blood-clots. The ureter was felt to be hard and considerably thickened, but there was no dilatation either of the ureter or of the pelvis of the kidney.

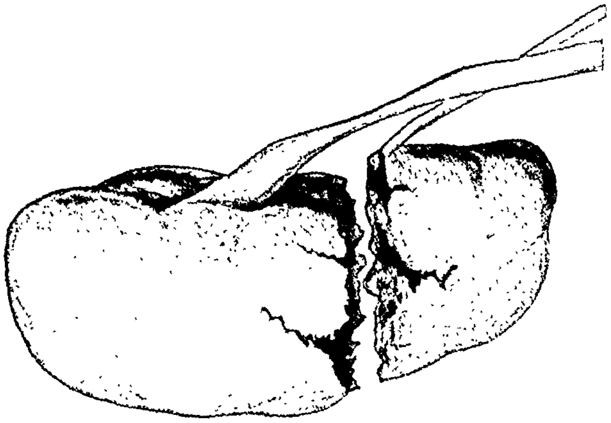
* Pathologic report by F. B. Gurd, M.D.
† Deceased, Jan. 14, 1911.

[1] Connell: The Journal A. M. A., March 25, 1911, p. 875.

As the condition of the patient was bad, no time was lost in careful examination. Drainage with tubes and gauze was done, the wound dressed, and the patient was returned to the ward. Shortly after the operation, the patient voided urine, and he continued to void normal quantities of clear urine. But he never rallied from the operation, and died thirty-six hours thereafter.



The subparietal rupture of a solitary kidney.

From the findings at autopsy, we concluded that, following the injury to the kidney, the upper segment continued to function until the gradually contracting blood-clot finally completely occluded the ureter.

The operation, by removing the obstruction, permitted the kidney to resume its function. The autopsy findings showed that there had been no hydronephrosis.

The autopsy was performed by Dr. F. B. Gurd, whose report is appended.

Autopsy.—This was performed six hours after death; a general examination of the body revealed nothing worthy of note with the exception of those parts in the neighborhood of the right kidney.

Over the loin on the right side is an incision 10 cm. in length, also a second incision of a similar length opening into the mid-line of the abdomen, its lower extremity being 8 cm. above the pubis.

On opening the abdomen, the posterior peritoneum appears to be deep reddish-black in color, the result of a blood-clot lying behind it. This appearance is especially marked in the neighborhood of the right kidney. Separation of this blood-clot, which measures from 2 to 6 cm. in thickness and is moderately friable, deep red in color and firm, discloses the right kidney. This organ is large (weight 380 gm.) and normally firm. Somewhat below the center of the organ from above downward there has been a solution of continuity, the separated surfaces lying about 4 cm. apart, the intervening space being filled with blood-clot and greyish friable masses, apparently necrotic material.

On the removal of the two portions of the kidney and the placing them in opposition, a more or less normal shaped large kidney is seen. The surface is smooth and normal in color, with the exception of an area 2 cm. wide on either side of the rupture. In these zones the surface is mottled deep red and greyish-yellow in color. On section the organ appears in general more or less normal, though somewhat pale. The cut surface bulges and exudes fluid blood. The cortex is thickened, measuring from 0.6 to 0.8 cm. in diameter. The glomeruli are somewhat more distinctly prominent than usual. Differentiation between the cortex and medulla is moderately well marked. The central portion of the kidney on either side of the line of rupture shows irregular deep purple, somewhat softer areas between which lie triangular yellowish portions with the apex pointing toward the medulla. These areas correspond to yellowish blotches seen on the surface.

At the point mentioned, namely 4 cm. from the kidney, the ureter is constricted measuring not more than 0.35 cm. in diameter for a distance of 4 cm. The wall of this ureter throughout its entire length is somewhat thickened.

The second ureter which is approximately half the size of the other arises from the lower portion of the kidney, at the point of rupture. No pelvis, and no calices are present.

Two sets of blood-vessels supply the kidney. One in the neighborhood of the upper, the other in the neighborhood of the lower ureter.

Absolutely no evidence of a second or left kidney can be found.

The bladder contains two normal-looking ureteral openings, the left opening being situated slightly further from the urethral opening than the right, giving the trigone an irregular appearance. The two ureters cross one another about 8 cm. above the bifurcation of the aorta, the right going to the upper pole of the kidney and the left to the lower. On removal, the kidney is found to weigh 400 gm., and, though large when the two portions are approximated, is normal in size. The kidney substance is moderately firm and somewhat paler than normal. On the upper surface of the lower portion several irregular, yellowish blotches are noted.

Anatomic Diagnosis: Congenital absence of left kidney; traumatic rupture of right kidney, retroperitoneal hematoma (perirenal).

Microscopic Examination of Kidney: A section cut from a more normal-looking area of the kidney shows an injection of the renal vessels and a few sclerosed Malpighian tufts. The cells lining the tubules are somewhat swollen and take the red stain with moderate intensity. The nuclei stain well. Within the tubules and about the glomeruli there is a moderate amount of granular red staining material (serum).

Other sections cut from the greyish purple area in the line of rupture consist of blood-clot, made up chiefly of necrotic blood-cells and kidney substance infiltrated here and there with polymorphonuclear leukocytes.

Section 3 cut from one of the yellowish nodules in the lower portion shows a necrosis *in situ* of the kidney substance surrounded by a zone characterized by injection of the blood-vessels and interstitial exudate of serum.

Microscopic Diagnosis: Acute nephritis
Infarcts of the kidney (traumatic).

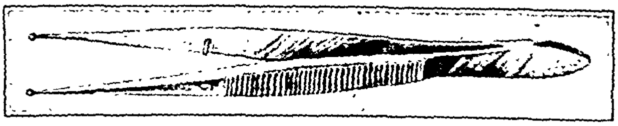
A NEW BLOOD-VESSEL FORCEPS

BERTRAM M. BERNHEIM, M.D.
BALTIMORE

The slightest scratch given the intima during the manipulations required in any blood-vessel work almost invariably spells failure in the form of a thrombus. Sharp-pointed instruments are, therefore, scrupulously avoided in all such work. Indeed, most men find their fingers the best and safest of all instruments.



Blood-vessel forceps with small ball-tipped ends

But since the work can at times be facilitated by a delicate pair of forceps, I have had one constructed which has a small, polished metal knob about the size of an ordinary pin-head on each end. These knobs enable one to grasp the vessel firmly without doing the slightest damage to the intima.

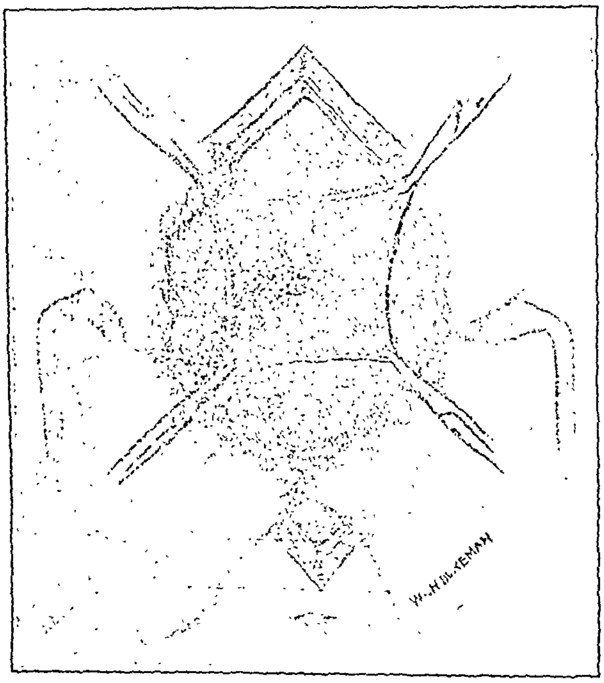
INTRAPERITONEAL CYSTOTOMY FOR TUMOR OF THE BLADDER *

W. H. DUKEMAN. M.D.
LOS ANGELES, CAL.

The conception of the operation of intraperitoneal cystotomy and the successful performance of the operation by Dr. F. B. Harrington of Boston in the year 1893 opened the way for the ideal surgical procedure for the removal of intravesical tumors of the bladder.

Harrington's detailed descriptive technic of the operation,[1] and full explanation of the feasibility of his method gave to the profession an operation in bladder surgery of great advantage over other methods now in vogue.

It is now eighteen years since Harrington first performed this operation, and only a very few surgeons have recognized its safety and ease of performance. The high rate of mortality in the surgery of the bladder for the removal of tumors, either by the suprapubic or perineal route, whether the growth be malignant or benign, does not give very encouraging results.



Abdominal wound, intestines and omentum, walled off with gauze pads, showing incision in the bladder, held open by forceps, exposing the tumor, urethra and right ureter. The left ureter is hidden behind the tumor.

Watson,[2] of Boston, in his tabulated report of 653 cases, shows the unsatisfactory results of surgical intervention by the perineal and suprapubic methods, and suggests the intraperitoneal operation.

Scudder and Davis,[3] of Boston, report four cases of the removal of tumors of the bladder by the Harrington intraperitoneal method, and all recovered.

The surgeons of St. Mary's Hospital, Rochester, Minn., in their collection of papers recently published, report fifteen cases of bladder tumors removed by the Harrington intraperitoneal method with but one death.

From the literature I have at command several other surgeons have reported single cases of resection of the bladder for malignant growths by this method, and with success.

As the intraperitoneal operation has not become as general with surgeons as its merits warrant, I trust that the addition to the list of another successful case, in which I operated recently by this method and which resulted in a most satisfactory and speedy recovery, will lead the cautious surgeon to give this method a trial.

REPORT OF CASE

History.—Dr. A., aged 68, retired physician, consulted me last November for slight hemorrhage of the bladder. His family history is unimportant as he has always enjoyed the average good health. Last November, he first noticed blood in the urine and some discomfort in the region of the prostate gland, with the desire for frequent micturition. The blood in the urine was not constant, but appeared only at intervals, accompanied with the occasional passage of small clots of blood. There was no profuse hemorrhage at any time.

Examination.—The prostate gland examined per rectum was normal for a man of his age. Microscopic examination of the urine showed blood, bladder epithelium, a few villous-like shreds, few crystals of calcium oxalate, no pus; the kidneys were normal. Diagnosis, possibly papilloma of the bladder.

I advised cystoscopic examination and sent the patient on March 28, 1911, to Dr. F. S. Dillingham, who reported the discovery of a growth, about the size of the first joint of the little finger, situated a little above and drooping down over the left ureter; any attempt to raise the tumor caused considerable hemorrhage. The tumor was attached by a broad base and its full length, which discouraged any attempt to remove it by operative cystoscopy. Diagnosis, tumor of the bladder, probably malignant. The bladder was washed out daily with boric acid solution and the patient sent to the Pacific Hospital.

Operation.—This was done April 5, by the intraperitoneal method. An incision was made from the pubes to within one inch of the navel, which gave ample room. The patient was placed in the Trendelenburg position and the intestines, omentum and abdominal incision walled off with gauze pads, leaving only the bladder exposed. The catheter was previously introduced into the bladder by the urethra and the bladder irrigated with boric acid solution. An incision, one and one-half inches, was made in the median line in the posterior bladder wall, and with clips holding apart the bladder incision, the tumor was nicely exposed to view. Its position had been accurately located by cystoscopy, being above and hanging over the left ureter; the lower point of attachment was about one-third inch above the ureter. Its base of attachment did not extend into the muscularis, and the tumor was very easily extirpated. The red-hot platinum cautery point was now applied to the raw surface at the seat of the tumor attachment, and the oozing of blood was completely controlled. The bladder was then carefully cleansed of all clots and mopped dry with gauze sponges. The little flow of urine from the ureters during the extirpation of the tumor, did not interfere in the least. The bladder incision was now closed. The first row of suture with No. 0 chromic catgut was inserted by the Connell stitch, taking in all the layers of the bladder wall, completely closing the incision, the mucous surface thereby being turned in and controlling all oozing of blood from the line of incision. The peritoneum was then enclosed over the first line of suture by the Cushing continuous method with No. 1 Pagenstecher linen thread. The catheter having been left in the urethra, the bladder was now irrigated with boric acid solution and slightly distended to test the line of suture, which proved to be water tight. The catheter was now withdrawn from the urethra, and about two ounces of the boric acid solution was left in the bladder. The gauze pads were then removed and the abdominal incision closed in layers. No drainage.

Histopathologic Report (by Dr. E. L. Leonard).—Epithelioma. Evidently low grade of malignancy.

---

* Read before the Los Angeles County Medical Association, June 2, 1911.

[2] *Watson*: Ann. Surg., December, 1905.

[3] Scudder and Davis: Ann. Surg., December, 1908.

Postoperative History.—The patient recovered from the anesthetic without vomiting and voided six ounces (urine and boric acid solution), three hours after the operation and without discomfort. The bladder was irrigated with boric acid solution three times daily for the first three days, then twice daily until the sixth day when the urine became almost clear, and by the tenth day the urine voided was all clear normal, and the irrigations of the bladder were stopped. The capacity of the bladder by the tenth day had increased to 8 and 10 ounces, while before the operation it was only from two to four ounces. By the eighth or tenth day all postoperative hemorrhage and irritability of the bladder had ceased. After the third day the patient partook of three regular light meals and was quite comfortable throughout the entire period of convalescence, amusing himself reading and relating funny stories to his attendants. He was up and around on the twelfth day and left the hospital on the seventeenth day. The postoperative temperature never arose above 99.4 F. and the pulse remained normal. After the operation there was no abdominal pain at any time, and no more discomfort at the neck of the bladder than had been present for months previously. The only inconvenience which the patient experienced after the intoxication from the ether had ceased was from the pulling of the abdominal stitches.

The surgeons who have adopted the intraperitoneal cystotomy operation for the removal of malignant tumors of the bladder, all agree in the praise of this method over the perineal and suprapubic routes.

The mortality from the cases reported so far, is less than 10 per cent., whereas by the suprapubic and perineal methods it is from 28 to 47 per cent.

In the hands of the careful operator, by the intraperitoneal route the danger of soiling and infecting the peritoneum is practically nothing. In the case here reported, there was no necessity for drainage and there was no postoperative annoyance to the patient; whereas every surgeon dreads the postoperative annoyance to which the patient is subjected by either the perineal or the suprapubic route, and the surgeon's anxiety relative to these postoperative dangers is practically eliminated by doing the intraperitoneal operation.

This single case, with the ease of approach and the ready access to the growth which the surgeon has at command to the base of the bladder, at once suggests the idea that, under favorable conditions, the enlarged prostate gland may be as easy and safely removed and all hemorrhage controlled by closure of the capsule by suture.

HEMORRHAGIC EROSIONS OF THE STOMACH

WITH THE REPORT OF THE AUTOPSY FINDINGS IN A CASE OF EINHORN'S DISEASE*

N. W. JONES, M.D.
PORTLAND, ORE.

Hemorrhagic erosions of the stomach from the viewpoint of the examination of the fasting organ is not an infrequent clinical finding. In 600 consecutive cases in which this routine examination was made as a part of general diagnosis, there were thirty-five cases, or 5.8 per cent., in which definite erosions of the gastric mucous membrane were found. As shown by the accompanying table, these cases were divided among the following disease conditions: Pernicious anemia, general asthenia, carcinoma of the stomach, carcinoma of the esophagus, cardiospasm, cardiosclerosis, dyspepsia nervosa, Schmidt's fermentation dyspepsia, Einhorn's disease, chronic anacid gastritis, chronic subacid gastritis, chronic acid gastritis, chronic gastrosuccorrhea, chronic gall-bladder disease, chronic intestinal catarrh, spastic obstipation, chronic salpingitis and chronic ulcer of the stomach. Two cases of so-called simple erosion, characterized by sudden severe gastric hemorrhage, afforded no fragments of mucous membrane either by vomiting or later by examination.

From a study of these cases the erosions group themselves logically into, (1) those without clinical significance, and (2) those with positive clinical significance.

Into the first group are placed the fragments of mucous membrane which are, for the most part, accidentally recovered. Chronic gastritis, together with the muscular contractions of the stomach and the trauma from the tube, has afforded thirteen of thirty-four cases. This trauma, together with the contractions of the muscular coats, has seemingly been the entire cause in all of the remaining cases with the exception of the two malignant ones, in which erosions were found. It has been noted also that these erosions were obtained only where there was more or less retching and resistance on the part of the individual. Study of most of the fragments in teased preparations or from sections, in those instances in which the erosions were large enough to be so treated, has not thrown any further light on their etiology. There is always a variable amount of small round cells between the gland acini, but it has been quite impossible to distinguish between round-cell infiltration and normal lymphoid structure. In one large erosion from a case of subacid gastritis "the cuticula and crypts were not broken or disintegrated, but in the deeper portions of the glands the cytoplasm stained faintly and was swollen. In places it seemed to be disintegrating and portions of the glands were missing. There was some small round-cell infiltration, but nowhere was it of marked degree." Other etiologic factors determined by Mintz, Wurtz and Leudet, Dieulafoy, Nauwerk, Gerhardt, Langerhans and E. Fraenkel, were not found.

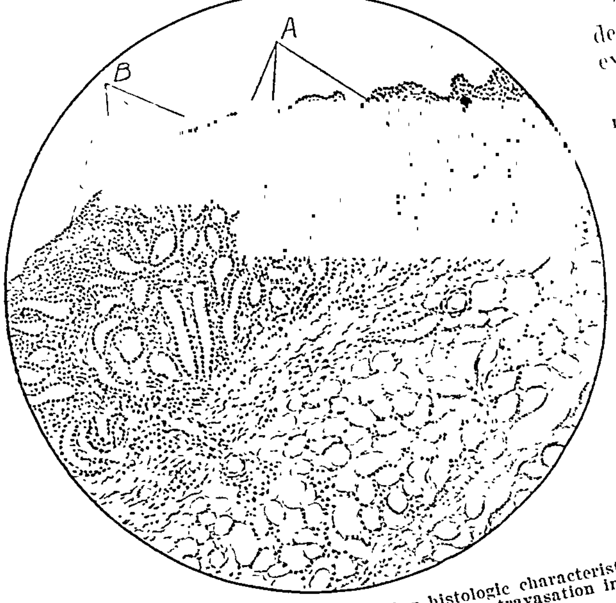
There are, however, two types of hemorrhagic erosions of the stomach of distinct clinical importance, which present fairly definite clinical pictures. They are (a) the so-called simple erosion of Dieulafoy and (b) the chronic and recurring type of erosion described first by Einhorn and now termed Einhorn's disease.

Of the simple erosion, which is characterized by sudden, severe, at times fatal hemorrhage occurring during normal health, usually without pain and with but little sickness, I do not wish to speak, excepting to emphasize the need of a better recognition of the condition and the employment of rational medical treatment. In one of the four cases seen by me death was hastened, if not actually caused, by surgical measures, and two of the three other patients were strongly urged by competent operators to submit to operation. I think it is now quite agreed among surgical writers as well as among physicians that acute bleeding from the stomach is a condition best handled by medical means and not by surgery. In 1901 Rodman reported thirty-two operations for acute gastric hemorrhage with nine deaths, a mortality of 40.6 per cent. In 1906 Laurent reported 93 per cent. recovery in his patients treated medically. A critical review of the literature since these dates bears out this contention more forcibly, and yet such patients are still being operated on. This fact, in my opinion, justifies the clinical grouping of this class of cases in such a way as will emphasize the importance of their treatment whatever the pathogenesis underlying the condition may be.

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

According to Einhorn, the disease which was described first by him in 1894, and which now bears his name, is a chronic condition characterized by diffuse stomach pain which comes on shortly after eating and is not influenced by pressure, vomiting or eating again; by a sense of great weakness, a rather rapid loss in weight. and, pathognomically, by the repeated presence of from two to four erosions in the wash water from the fasting stomach. Einhorn's belief that this clinical picture was the expression of a distinct disease has been upheld by Mintz, Berger and others. Pariser, Nauwerk and Elsner, on the other hand, have maintained that the basis of the picture has been a chronic gastritis, the ordinary symptoms of which have been forced into the background by the periodic occurrence of the erosions and the bleeding. Owing to the entire absence of postmortem examinations of such cases, the following typically illustrative case which came to autopsy is given briefly in detail, together with the anatomic findings:



Reproduction from drawing showing histologic characteristics of tissue. A, remnants of gland acini; B, blood extravasation in areas of dense, small round-cell infiltration.

History.—Mr. D., a business man, aged 57 years, began twenty years ago to have, with the coming of each winter, periods of illness characterized by a diffuse sense of burning in the stomach after eating, sometimes on rising, a rapidly developing weakness, paleness and loss of weight. At times there was some nausea and the regurgitation of clear fluid which was not especially sour to taste. All foods produced distress. There was no local tenderness, no fever, chills or sweating. The bowels were regular. Each year the illness lasted several weeks, usually in bed with restricted diet. More or less paleness and weakness would last until warm weather set in, when he would regain his health rapidly, his anemia would disappear and his stomach would again tolerate any kind of food without discomfort. The patient believed a causal relationship existed on the part of the cold and always dreaded the approach of winter. During the illness of the year preceding that of his death occult blood was found in the stools. His last illness came on as they always had before and was of several weeks' duration. Blood was again found in the stools Dr. Mackenzie tells me that blood examinations showed a very severe grade of a chlorotic type of anemia. The patient had weighed 202 pounds before his illness began but had lost much flesh during it. His own personal history and that of his family were negative in all respects.

Necropsy.—Through the courtesy of Dr. Mackenzie I made a post-mortem examination on Dec. 20, 1909, six hours after death. Briefly the anatomic findings were as follows: The body was that of a tall, heavily boned, greatly emaciated middle-aged man. The panniculus was pale and scanty; the peritoneum was smooth and glossy. All parenchymatous organs were very pale and dry. The heart and lungs were otherwise negative. Very small scattered atheromatous patches existed in the beginning of the arch of the aorta. They were absent throughout the course of the abdominal aorta. There was no gross evidence of terminal infection. The bone-marrow of the ribs was pale in color. The intestine and colon were more or less filled with dark, tarry content that contained much blood. The stomach was of normal size, blanched, and contained a little turbid fluid. Over the mucosal surface a moderate amount of greyish, somewhat blood-stained, tenacious mucus was found. On the posterior wall about midway between the cardia and the pylorus were seen five small eroded areas with hemorrhagic margins and bases. They were superficial in character, not extending to the submucosa, and varied from the size of a split pea to 1.5 cm. in length and 1/3 cm. in width. No eroded vessels could be found.

The stomach was given to Dr. Roberg of the medical department of the University of Oregon for histologic examination. He reports as follows:

> The mucosal surface of the organ is pale yellowish in color. mottled by several deeply colored and rather circumscribed areas. Sections for examinations were taken through both the pale and the darker portions of the stomach-wall. Microscopically, the dark areas show no difference in appearance from the other. They are pigmented areas of submucous hemorrhages, the coloring of which is derived from dissolved hemoglobin deposited in the interglandular tissue and in the secreting cells of the gastric glands. The interstitial tissue of the epithelial layer of the mucosa is the seat of a dense, small round-cell infiltration. This infiltration is diffuse and more marked in the surface of the mucosa. The deposit of these small round cells is so dense that in many cases the stomach glands have been completely obliterated. Scattered throughout this dense infiltration are islands or portions of glands. Their lumina are distended to two or three times the normal size. The cell cytoplasm is granular and disintegrated and in many places the lumina are filled with a cytoplasmic debris. In the fundus region no differentiation of the gland cells occurs into parietal and chief cells. All gland-cell nuclei stain less deeply than normal. The capillaries in the mucous membrane are markedy dilated along the basement membrane and, in the region of the crypts, show a diffuse extravasation of blood. The blood-vessel plexuses in the submucosal and muscular layers show a thickening of the walls and a slight congestion. The muscular layer, submucosa and muscularis have to a slight degree an infiltration of small round cells.

I submitted also to Dr. Roberg for histologic examination three large erosions from a typical case of Einhorn's disease which I have had under observation for over three years and which I have previously reported. His findings are as follows:

> The gastric crypts and cuticular border of the mucosa are quite intact. The neck and fundus portions of the gastric glands are displaced and partly obliterated by a small round-cell infiltration not unlike that described in the previous case but not so dense. The destruction and displacement of the glandular elements, although considerable, are likewise not so marked. Interstitial hemorrhage and congestion are absent.
>
> Thus the microscopic examination of the two cases presents the picture of a form of chronic gastritis characterized (1) by a dense small round-cell infiltration in the interstices of the glandular elements, which when extensive obliterates the gastric glands by pressure; (2) by the disintegration of the cutic-

ular portion of the mucosa as the crypts are displaced by the small round cells; and (3) by the fact that with the disintegration of the cuticula and crypts the congested vessels are exposed and ruptured, which accounts for the gastric hemorrhages occurring during the clinical course of the disease.

An entire absence of proliferation of the connective tissue elements, the engorgement of the superficial blood capillaries and the manner in which the gland cells are destroyed sharply differentiate the process from ordinary chronic gastritis. The claim, therefore, of Elsner and others that the disease is one of ordinary gastritis with the factor of erosion formation added to it is no longer tenable, and neither, on the other hand, is that of Einhorn, for the process must be classified as a type of chronic gastritis. It is, in fact, a chronic, non-proliferative, hemorrhagic gastritis.

In general, I believe it will be well to retain this clinical grouping of hemorrhagic erosions, and to consider them, clinically speaking, as disease entities for the sake of defining their relation to other types of gastric hemorrhage. Simple erosion, on the one hand, probably possesses a manifold etiology. Whether Einhorn's disease likewise does, only further autopsy findings will determine. From the similarity of these two cases, however, it is probable that its pathology will be found to be the same in others.

TABLE OF SIX HUNDRED CASES AND RELATION OF STOMACH EROSIONS TO THEM

ABSTRACT OF DISCUSSION

Dr. Robert T. Morris, New York: In these days when so much credit is given to proper stomach surgery, I wish to emphasize a point made by Dr. Jones that hemorrhagic erosions of the stomach are not cases for the surgeon. Whatever credit comes to surgeons is from wise selection of cases. Surgery does not at all comprehend the question of gastric erosions and does not give relief because the original condition persists. Again, there are the shock and other features which were incidental to operation, features that are not desirable. There was one point, however, that Dr. Jones did not bring out and one which I believe to be very important. We should learn more of the early septic history, and especially of the ordinary medical treatment that was employed at the time the erosions occurred. Of course, the patients must have treatment when these erosions of the stomach occur, but the earlier toxic history should be kept track of in all these cases. We should remember that hyperchlorhydria and hypochlorhydria are symptoms like coughing or sneezing. The hormones send wrong messages to the secreting glands. What reason have we for believing that excreted toxins are basic factors in these erosions? What is found in the peritoneum of the vicinity gives us a clue? We all have found peritoneal adhesions so common in the pyloric region that we must assign some significance to them. We often meet with cases of adhesions, "cobwebs in the attic of the abdomen," which are due apparently to the excretion of toxins by the liver; in some cases the lesion might be due to the actual excretion of bacteria, chiefly of the colon-bacillus group, which pass the liver unharmed at times, but set up trouble in the bile-tract. The endothelium desquamates, lymph is excreted, coagulation occurs and adhesions are then formed and gastric disturbances follow. These hieroglyphics most of you can read and must read. When these hieroglyphics in *bas relief* occur in the peritoneum, the "cobwebs in the attic of the abdomen," we must look for an explanation in the toxic influences preceding erosion. Such toxic influences result in spasm of the terminal arteries situated in this region. Please do not forget the terminal arteries, for we are dealing with them. The toxic spasm of the terminal arteries here results in cell infiltration and other pathologic conditions, such as Dr. Jones has described in his paper.

In the treatment of hemorrhagic erosions of the stomach, surgery should not, I believe, be considered at all; medical treatment alone should be employed; any operation in these cases must result in disaster. If we hark back to the original cause I think we shall find that hemorrhagic erosions of the stomach are the result of excreted toxins.

Dr. J. F. Hultgen, Chicago: Erosions of the stomach are not considered sufficiently in connection with the constant anemia which one meets with in these cases. This fact suggests to me that there might be an anatomic cause for this condition—the symptom-complex might be due to the anemia itself; it might be due, as Dr. Morris has suggested, to some toxic process. The anemia *coexistent or coexisting* in these cases has not been thoroughly inquired into; more investigations should be made in order to bring out this matter. As a matter of fact, the anatomic basis, so far as was shown by Dr. Jones, was not sufficient to explain the clinical course of the disease. I believe that the gastric hemorrhage from the erosion is nothing but a symptom, and that the underlying morbid process might be of hemolytic nature or of toxic origin.

Dr. Philip King Brown, San Francisco: This condition of hemorrhagic erosions of the stomach is not recognized easily. Hemorrhage occurring in association with pain might be the result of chronic disease of the appendix, so fully described by Moynihan several years ago. He reported twelve cases, the symptoms of which were classical of gastric ulcer; at operation no ulcers were found. In each instance, however, there was found a diseased appendix. When the appendix was removed in these cases all the symptoms of gastric ulcer disappeared. It was my lot to recommend for operation practically the same kind of a case; this patient presented symptoms that made one feel quite positive of his diagnosis. The individual had been under the care of Dr. Boas and Dr. Ewald and other stomach specialists of note. They all made a similar mistake in the diagnosis. The symptoms were entirely gastric and hemorrhages were quite frequent. Under my care and while on a strict Lenhart diet, with the usual subnormal temperature, there suddenly developed a rise of 4 or 5 degrees above the normal. Evidently there was some pathologic condition in the appendix, as the fever was accompanied by pain, spasm and tenderness at McBurney's point, but it did not seem wise to operate on her at the time. Later at operation a very careful exploration of the gastric region was made, but nothing was found at all. The appendix was examined and removed, because adjacent to it was found a calcified gland and there were other evidences of old disease of this organ in the way of firm adhesions and partial occlusion and thickening. No really satisfactory explanation of the cause of hemorrhage from the stomach in these cases has yet been given. Whatever statements have been made thus far are not at all satisfactory to those who are looking for an explanation, but the point of gastric hemorrhage without ulcer from disease of the appendix is well established and should be borne in mind.

Dr. N. W. Jones, Portland, Ore.: In an exhaustive search of the literature on Einhorn's disease there are found no records of cases coming to autopsy. The pathology of the case reported by me seems to be distinct, but it needs verification by other cases. This condition is entirely distinct from those septic conditions in which stomach bleeding has occurred, as reported by Moynihan and Dieulafoy; and, it would seem to me, can have no relation to them. Its pathogenesis is not known. It does not seem to be that of ordinary chronic gastritis.

BUBONIC PLAGUE

WITH SPECIAL REFERENCE TO THAT OF GROUND SQUIRREL ORIGIN *

GEORGE W. McCOY, M.D.
Passed Assistant Surgeon, U. S. Public Health and Marine-Hospital Service
SAN FRANCISCO

Bubonic plague is a subject with which, fortunately, few of us have to deal. The practitioner in California, however, especially if his lot has been cast in the rural communities, must always keep the disease in mind when any acute febrile case comes under his observation. It is my intention to discuss only the isolated cases that occur in the country districts. Those that have been seen in San Francisco and in Oakland at various times between 1900 and 1908 were clearly associated with the presence of plague among rats, while the cases to which I particularly refer are associated with, and due to, the prevalence of the disease among ground squirrels (*Citellus beecheyi*). While plague in man when contracted from these animals is probably not essentially different from that derived from other sources, usually from rats, the cases that have come under observation are sufficient in number to justify us in examining them with care, especially as they are due to infection from a source that is unusual in other countries.

Two or three years after plague had been recognized in San Francisco, several cases of the disease occurred among persons living in the rural districts in the country across the bay from San Francisco. Surgeon Rupert Blue, of the Public Health and Marine-Hospital Service, noted in one or two instances that the disease occurred in those who had hunted ground squirrels a few days prior to the onset of the illness, and he suggested that since there had been no contact with human plague, and no known opportunity for infection from rats, the disease might be present in the squirrels, and be communicated from them to man.

During the past three years I have conducted the bacteriologic investigations in eleven cases of plague of ground squirrel origin. Seven of these patients I have seen clinically, and verified the diagnosis by laboratory methods, while in four the diagnosis was made from the bacteriologic examination of tissues taken at autopsy and sent to the laboratory. Six of these patients, all from the known infected zone, gave a clear history of handling ground squirrels within a week prior to the onset of the symptoms. Five gave no such history although they had been in vicinities where plague was known to exist among the ground squirrels at the time, or where it was demonstrated as a result of the investigations set in motion by the discovery of the disease in man. Of these eleven patients, seven were young men between the ages of 13 and 37; one was a boy aged 5; another, a boy aged 7; while two were young women. Six of these proved fatal, while five recovered.

Clinically there were three groups: The severe acute, the mild acute, and the subacute or pyemic. Six belonged to the first group. A typical history of one of these is as follows:

> About a week before becoming ill, the man had been squirrel shooting. The first complaint was of pain in the back and in the groin. There was great prostration. The temperature was 101.4 F., pulse 100. The second day, a swelling was made out in the femoral region. The third day, the patient was delirious and remained so until he died. The highest temperature recorded in this case was 103.8 F. but it usually goes to 105 F. or over. Death occurred on the fifth day of the illness.

One of these cases was rather unusual in that recovery occurred after invasion of the blood-stream by the plague bacillus. The evidence of septicemia was the recovery of the bacillus from the blood, and the development of secondary buboes in the regions of the various peripheral lymph glands.

The mild cases were four in number: all ending in recovery, but none was so mild as to justify calling it pestis minor. The history of the most recent case is as follows:

> There was no evidence of contact with squirrels, but the patient, a girl, lived in a territory that was known to be heavily infected. The first symptoms were headache and fever. These were followed by pain and tenderness in the right groin. The disturbance was so mild that it was thought sufficient to consult a physician by telephone. However, when improvement did not occur, the patient was visited by the medical attendant, who found a temperature of 104 F. There was a bubo in the femoral region. One week after the onset of the illness the glands were removed under an anesthetic. The patient made an uneventful recovery, never having been regarded as dangerously ill.

The subacute class is represented by only one among the squirrel cases that have come under my observation. This has been reported in detail by former Acting Assistant Surgeon W. B. Wherry and myself.[1] These cases of subacute or pyemic plague are seen occasionally in epidemics of rat origin.

> The patient was a youth, aged 13, who had been squirrel shooting about five days prior to the onset of the symptoms. The illness began with headache and vomiting. The next day the temperature was 104 F. Forty-eight hours after the onset of the symptoms, the glands in one axilla were found to be much enlarged and very painful. The nature of the dis-

* From the Federal Laboratory, San Francisco.

[1] Wherry, W. B., and McCoy, G. W.: Jour. Infect. Dis., November, 1909, vi, 5, p. 670.

case was not suspected and the glands were excised. On the fifth day all of the superficial glands became swollen and tender. The sputum was blood-tinged, and the patient was evidently quite ill. On the tenth day a pustular eruption appeared and plague bacilli were found in one of the skin lesions. The patient became septic and died on the sixteenth day of the illness. At the post-mortem, caseo-purulent foci were found in the lungs, liver and kidneys, as well as in the lymph glands.

No case of primary pneumonic or primary septicemic plague attributable to ground squirrel infection has come under observation.

On account of the importance of a diagnosis that cannot be impeached, it is required that all of these cases be verified bacteriologically; a few words may be said, however, about the clinical diagnosis. The onset is usually with fever, headache and pain in the back. Nose bleed often occurs. Several of the cases gave a history of an initial chill. The temperature is usually about 102 F., or 103 F. when the patient is first seen by a physician. A glandular swelling appears, sometimes coincident with the onset of the other symptoms, but usually a day or two later. In eight of the eleven cases, the primary bubo was in the axilla; in three it was in the groin. The gland involved is tender. The outline is lost in an edema that surrounds the parts. Fever and other general symptoms continue from five to eight days, or even longer. In the only cases in which recovery has taken place and the glands had not been excised, suppuration occurred. In the fatal cases, the patient usually dies while the glands are caseous and hemorrhagic and before pus has formed.

It is a pleasure to be able to state that although the disease is rare our recent cases have been recognized as suspicious by attending physicians and by the surgeons who removed the glands.

The bacteriologic diagnosis is made by the examination of a piece of the gland removed at operation, of fluid aspirated from a gland, or of tissue removed at the necropsy. When the smears show a considerable number of pest-like bacilli, a provisional diagnosis is made. The bacillus is isolated by cultural methods and laboratory animals are inoculated. It is the rule that the media inoculated from the bubo show an enormous number of colonies of *Bacillus pestis*, but in one case only six colonies appeared on the three tubes used, showing apparently that bacilli were very scarce. The growth was highly virulent, though the case was a mild one.

An experiment was undertaken for the purpose of ascertaining whether there was any difference in virulence for laboratory animals of the cultures isolated from the mild and from the severe cases of plague in man. Without entering into the details of the experiment I may state that the bacilli derived from mild cases were quite as pathogenic as those obtained from the severe and fatal cases. In other words, the severity of clinical manifestations is due to the varying resistance of the individuals rather than to a difference in the virulence of the organisms causing the disease.

Whenever practicable, the cases are treated with antipest serum, but the majority have come under observation too late to be benefited by it. The other treatment is purely symptomatic.

So much for the subject as regards human plague. I shall now discuss briefly the more important problem, the infection among the ground squirrels. The first proof of plague among the squirrels was obtained in the summer of 1908. Since that time, by an extensive investigation of these animals throughout the state, it has been found that the disease is probably confined to ten counties lying east and south of San Francisco Bay. This work has been carried on by the Public Health and Marine-Hospital Service, the immediate direction being in the hands of Surgeon Rupert Blue. The squirrels are shot and sent to the laboratory where they are dissected and examined.

In the rodents, the disease causes well-marked and readily recognized lesions which vary greatly. The larger percentage of cases are distinctly subacute or chronic, while a smaller number are of the acute type.

The pest bacillus isolated from infected squirrels is, morphologically, culturally and bacteriologically, in every way identical with that isolated from man and from rats. As to its pathogenicity, I may say that the organism appears to be a trifle less virulent than those from other sources; however, no definite statement is to be made on this point.

A very interesting observation is that many of the squirrels from the zone in which plague has prevailed for several years are relatively immune to laboratory infection with *Bacillus pestis*.

During the routine examination of these rodents, we have encountered a disease, the gross lesions of which bear a very strong resemblance to those of plague.[2] It is readily differentiated by bacteriologic methods.

The subject of the transmission of the disease from one squirrel to another, and from these rodents to man, is a very important one, and I regret that we have no conclusive evidence about the mode of infection. We have been able to show experimentally that plague may be carried from squirrel to squirrel by means of fleas. It may also be transmitted by feeding. What evidence we have, largely dependent on the location of the bubo, leads us to suspect that the disease is conveyed in nature by fleas, and possibly by other ecto-parasites. Briefly, this evidence, the importance of which in rat plague has been demonstrated by British workers in India, is as follows: In natural infections in rodents the bubo is found in the region of the peripheral glands, cervical, axillary, inguinal or pelvic. This agrees with the distribution of buboes in squirrels, rats and guinea pigs that have been infected experimentally by fleas, while in rodents infected by feeding, the buboes are always in the neck or in the mesentery. It will be noted that the neck buboes may be acquired in either way, i e., through fleas or by ingestion.

In one of the cases the patient, a boy, was bitten on the hand by a squirrel, and since the primary bubo occurred in the axilla on the same side, it seems reasonable to suppose that the bite infected the boy. This is rendered probable as many plague squirrels have lung lesions. Most of our cases have occurred during the summer months, which is the season of squirrel hunting. That the mere handling of an infected animal is not very dangerous is shown by the fact that the employees of the service have handled hundreds of plague squirrels without an accident, merely taking precautions against fleas.

The predominance of axillary buboes in human cases would appear to be accounted for by the fact that in handling infected squirrels which may carry parasites, the hands and arms would be more exposed to the attacks of the insects than other parts of the body. We cannot assert positively that parasites carry the disease to man, but it seems to be the most reasonable explanation.

---

[2] Pub. Health Bull. 43, U. S. Public Health and Marine-Hospital Service, Washington, D. C., 1911.

The question might be asked why so few cases of plague in man have resulted from the extensive infection among the ground squirrels. The answer is not quite clear, but leaving aside such matters as failure to recognize or to report the disease, it may be stated that the evidence offered by the examination of infected squirrels leads to the belief that a comparatively small percentage of them have the bacilli circulating in their blood in any considerable numbers. Of about 250 infected squirrels of which we have complete records, only about one-fourth could have been regarded as septicemic at the time they were shot.

The chief menace of squirrel plague is, as has been recognized from the first by all of those who have occasion to deal with the subject, the danger of the infection of the rats of the cities, which might lead to more or less extensive outbreaks among human beings. The discussion of this problem is not within the scope of the present paper.

I wish to acknowledge here my indebtedness to the various physicians in the state in whose practices the cases occurred and who furnished me with the clinical data.

ABSTRACT OF DISCUSSION

Dr. Edward F. Wells, Chicago: The paper of Dr. McCoy is a very important one bearing on bubonic plague with special reference to ground squirrel origin. I should like to ask him for what purpose the animal was killed and what becomes of the carcass? Also does each species have special fleas of its own?

Dr. G. W. McCoy, San Francisco: The squirrels examined have all been killed or caught by hunters employed by the Public Health and Marine-Hospital Service for the purpose of securing specimens in order that the extent of the zone of plague infection may be determined accurately. As to the matter of fleas, in a general way we may say that each species has a special flea of its own, and, judging from what we have learned by experimental work on the lower animals, fleas from one species are capable of carrying the infection to other species, in addition to carrying it among the members of the species to which the particular flea properly belongs.

METHOD OF INFECTION IN PNEUMONIC PLAGUE *

RICHARD P. STRONG, M.D.
AND
OSCAR TEAGUE, M.D.
American Delegates to the International Plague Conference, Mukden, Manchuria
MANILA, P. I.

The object of the present investigation in Manchuria was to show, first, whether in cases of pneumonic plague pest bacilli become disseminated into the air by the vapor arising from the breath, as in ordinary or in dyspneic respiration, and second, whether the organisms are disseminated by moderate attacks of coughing of pneumonic plague patients in whom the cough does not result in the expulsion of particles of sputum visible to the naked eye. In the course of the experiments on a number of occasions during coughing, small droplets or larger particles of sputum, visible to the eye, were raised and touched the surface of the media on the plate cultures which were exposed before the plague patient. The study of these culture obviously is not included in this investigation. The cultures were invariably exposed before cases of pneumonic plague with bloody sputum, and in which enormous numbers of plague bacilli had been shown to be present. All of the patients, before whom the plates were exposed died of plague infection within twenty-four to forty-eight hours from the time of the exposure. Twelve series of experiments were performed in which seventy-eight plate cultures were exposed and the microorganisms which developed on them studied.

The experiments were performed in the following manner:

The plates were sterilized in the hot-air sterilizer within a metal plate-holder; they were then removed, the cultures poured in the usual way, and as soon as the medium was sufficiently hard, were replaced within the plate-holder and taken to the bedside of the patient, in the sputum of which plague bacilli had previously been found. All of the attendants were asked to retire from the room in order that as little dust as possible might be present in the air. The condition of the patient before whom the plates were exposed was noted, and during the exposure of the plate, the character of the respirations were particularly observed and notes made of whether coughing or talking occurred. The time of the exposure of the plate and the distance from the patient were also recorded in each instance. The plate was then returned to the holder and placed in the incubator. After twenty-four hours the cultures were examined for the appearance of colonies and their number counted, but the plates were not opened until after forty-eight or seventy-two hours. The colonies were then again counted and carefully studied. Any of the colonies which in any way resembled colonies of the plague bacillus were transplanted to agar slant cultures. The morphology and the staining properties of these organisms were then studied.

In every instance in which the morphology was at all similar to that of the plague bacillus or the organism decolorized by Gram's stain, it was inoculated either into mice or guinea-pigs. In a few cases the colonies were so thick on the plate, or surface growths from air contamination with bacteria were so extensive that the separate organisms could not be isolated and studied. In these instances a suspension of the whole plate was made and a portion of the suspension either rubbed over the scarified abdomen of a guinea-pig or inoculated subcutaneously into a mouse. On several occasions in which it seemed hopeless to determine whether the plague bacillus was present or not on the plate, owing to the extensive contamination of the culture with air organisms, the animal so inoculated died of plague. In a few instances the plates were discarded because of very extensive contamination from air organisms which covered the whole surface of the plate, with a very thick layer of growth. During the colder weather in Mukden the plates exposed before plague patients during ordinary respiration were frequently entirely sterile. The plates were exposed vertically before the mouth and nose of the patient; the time of exposure varied between two and five minutes; generally the shorter period was employed. In the experiments performed in the earlier part of the investigation the plates were held at a distance of from 2 or 3 inches to 3 or 4 feet from the mouth of the patient. Later in the experiments, when it became evident that in cases without cough during exposure, no plague bacilli were encountered at the greater distances, they were exposed at a distance of from 2 to 4 inches in front of the mouth and nose.

We shall not present here, in detail, the results obtained with each plate culture, these will appear when publication of the entire results are made. In thirty-nine instances the plates were exposed before patients who did not cough during the time of exposure, and notwithstanding the fact that many of the patients suffered with marked dyspnea and advanced edema of the lungs, in only a single instance was the plague bacillus encountered in one of these plate cultures,

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911

although in a number of the experiments the surface of the media was visibly wet by the vapor arising from the breath.

In this one case the conditions of the experiment were as follows:

> Three plate cultures were all exposed at a distance of about 3 inches, and for two minutes before a patient with marked dyspnea who died two hours afterward. A suspension of the bacterial growth which developed on one of these plates, and which covered almost the entire surface of the plate, was made, and a portion rubbed over the abdomen of a shaved guinea-pig with the side of a scalpel and the skin then freshly scarified. The animal died of plague infection six and a half days later; there were inguinal buboes and miliary nodules in the spleen.

The animals inoculated with the colonies from the other two plates exposed in exactly the same manner did not develop plague infection. The results obtained from this one plate are different from those obtained from the remaining thirty-eight plates. Two possible explanations of the result suggest themselves: (1) that the plague bacilli reached the plate exposed before the patient in the plague ward in some other way than by the expired air; (2) that the plate was infected with plague bacilli by the droplet method through the forced expirations of the patient during the time this one plate was exposed.

The remaining number of plate cultures, thirty-nine, were exposed before patients who coughed during the time of exposure, and in fifteen instances, colonies of plague bacilli developed on the exposed plates. In some cases more than 100 colonies of this organism were obtained on the cultures after a single cough, sometimes in almost pure culture.

Guinea-pigs in which the abdomen had been shaved and extensively scarified just before the time of the experiment, were exposed before three cases of pneumonic plague for a period of two minutes and at a distance of 2 inches from the mouth, the abdomen being placed toward the mouth. The breathing of the patient in all of these experiments was labored, so that the hair of the guinea-pigs waved back and forth in the breeze made by the expired air, but no cough occurred during the time of the exposure. The animals remained alive and did not develop plague infection.

The results of all these experiments are in accord with those of Nägel, Flügge and their pupils whose experiments showed conclusively that by currents of air bacteria are not lifted from moist surfaces, but that in the coughing of tuberculous patients the *Bacillus tuberculosis* might become disseminated into the air suspended in fine droplets (drop infection).

However, these observers concluded that in the case of pulmonary tuberculosis this was not a very practicable or frequent method of infection. In pneumonic plague the conditions are very different, owing to the enormous numbers of plague bacilli which are present in the lungs and bronchi. In our experiments, performed with cases of marked pulmonary edema, the conditions were also different. The opportunities for infection by means of the droplet method must be very great in a pneumonic plague ward.

CONCLUSIONS

1. During normal and dyspneic respiration of primary pneumonic plague patients, plague bacilli are not usually expelled by means of the expired air.

2. During the coughing of such patients, even when sputum visible to the naked eye is not expelled, plague bacilli in large numbers may become widely disseminated into the air surrounding the patient.

3. As to the distance from the patient that the air may be infected by droplets containing plague bacilli, this varies largely with the strength of the cough, the amount of mucus in the throat and larynx at the time, and the currents of air in circulation in the ward.

4. The idea that infection of doctors, nurses, attendants, etc., in plague hospitals is caused entirely by particles of sputum expectorated by the patient and visible to the naked eye, is erroneous. It follows from these experiments that the wearing of masks and the proper covering of any surface of the skin where fresh abrasions are present are important personal prophylactic measures in pneumonic plague. It also follows that the eyes should be protected against this manner of conjunctival infection by proper glasses.

5. Articles of clothing worn in the wards should immediately be sterilized after removal, since, even though no particles of sputum may be visible on them, plague bacilli may be present.

PREVENTIVE MEDICINE SECTION COMMITTEE REPORTS

REPORT OF COMMITTEE ON METHODS FOR THE CONTROL OF PLAGUE *

Your committee begs leave to report as follows: Plague infection exists to-day among the ground squirrels—rural rodents—of California. No infection, in man or rodent, has been found in the centers of population in California since the fall and winter of 1908, and none in the state of Washington since February, 1910, the last human case having occurred in Oakland, July 17, 1908. In the past two years more than 200,000 rats have been collected in San Francisco and Oakland and examined in the laboratory, without yielding a single case of infection. Your committee, therefore, is of the opinion that all traces of the disease have been eradicated from the cities about the bay. Notwithstanding the successful outcome of the anti-plague campaign the Public Health and Marine-Hospital Service intends to enforce prophylactic measures in these centers for a considerable period longer. These operations include building reforms, rat-proof construction, rat extermination ashore and aboard vessels, and such other methods as tend to exclude plague.

Numerous foci of infection have been found in the rural districts, affecting large areas in the central and coast counties of the state. Human cases have occurred in four of the counties covered by the epizootic, and in each case there existed an intimate association with ground squirrels. The epidemiologic observations and the laboratory work of the officers of the Public Health and Marine-Hospital Service show that these animals are the enzootic hosts of plague in America; in other words, they keep *B. pestis* alive until a favorable opportunity arrives for a human outbreak.

Methods for the control of the present situation should include the following measures:

1. The prevention of spread from rural to urban rodents by limiting the chances of contact and interchange of ectoparasites between the two. This suggests (a) the maintenance of squirrel-free zones around the centers of population; (b) prohibiting the marketing or traffic in rodents; (c) general rat destruction in the cities.

2. The prevention of a wider spread among rural rodents and the ultimate invasion of the eastern states by such means as the following: (a) destruction of known enzootic foci in the various counties; (b) general rodent extermination throughout California and the near-by states.

---

* Read in the Section on Preventive Medicine of the American Medical Association, at its Sixty-Second Annual Session, held at Los Angeles, June, 1911.

This work should be continued where now in operation and inaugurated at once throughout the United States, and made a continuous, systematic measure. It should include the adoption of building ordinances, garbage regulations and systematic extermination in all cities but more especially in the sea-ports. There should be instituted without delay, in all cities, a system of collection and examination of rats so that an epizootic could be detected in time to apply preventive measures before the occurrence of human cases.

Your committee desires to commend the action of certain county supervisors in California for the energy displayed and wisdom shown in undertaking general rodent extermination at this time. It is an example that might well be followed by the health boards and other officials of the western states.

Rupert Blue, M.D., Chairman, San Francisco.
Elmer E. Heg, M.D., Seattle, Wash.
William F. Snow, M.D., Sacramento, Cal.

METHODS FOR THE CONTROL OF PLAGUE WITH SPECIAL REFERENCE TO ADMINISTRATIVE DETAILS

ARGUMENT SUPPORTING THE COMMITTEE'S REPORT *

RUPERT BLUE, M.D.
Surgeon Public Health and Marine-Hospital Service
SAN FRANCISCO

It would obviously be impossible in a brief paper to discuss the entire problem of plague control, but the general principles may be illustrated by a review of the measures that proved of value in the San Francisco campaign. A consideration of the methods for combating the further advances of the disease in this country is of special interest and should not be omitted from to-day's program.

There are some special considerations to be borne in mind in regard to this disease. Bubonic plague is primarily, and *par excellence*, a disease of the lower animals, human cases being mere accidents in the progress of an epizootic, and produced in most instances through the bites of infected fleas. There are other channels by which man may receive infection, such as inhalation and ingestion, but with these we are not concerned for the present inquiry into the rôle which animals have played in connection with the spread of plague showing that epidemics among men are invariably dependent on epizootics among animals.

The principal offenders of this zoologic group in California are the families *Sciuridæ* and *Muridæ*. Ground squirrels (*Citellus. Spermophilus*), tree squirrels (*Sciurus*) and marmots (*Arctomys*) compose the former, while of the latter there are numerous genera in this country, such as the domesticated rats (*Mus*) and the wild wood-rats (*Neotoma*) of the western, middle and southern states. A knowledge of the life-history of these animals is essential if the sanitarian would keep abreast of the times in all that pertains to his professional duties.

It can be laid down as a principle that measures directed against persons and things other than rodents will not check an epidemic of *bubonic* plague. In all recent epidemics much valuable time has been devoted to the enforced isolation of infected persons, the inoculation of those exposed to the disease, and the disinfection of infected houses, without adequate returns for the labor expended. These procedures, however, are efficient and can be relied on to stay an outbreak of *pneumonic* plague. Recent experiences in Harbin, Manchuria, show that such measures had an immediate effect in reducing the morbidity and finally in eradicating all traces of the epidemic.

Let it be understood, however, that I do not undervalue the importance of isolation and disinfection in anti-plague work. They should be enforced as auxiliary measures, and because of the fact that a bubonic case may become secondarily pneumonic and highly infectious and contagious.

MEASURES FOR COMBATING PLAGUE IN CENTERS OF POPULATION

The first requisite is a special plague organization having no duties other than those for which it is called into service. This should be placed under the direction of an expert sanitarian who, preferably, should have no local or political affiliations in the infected city.

For the convenience of administration the city should be divided into districts. Each district should have an experienced medical officer at its head, a sufficient number of sanitary inspectors, laborers and all necessary equipment for the expeditious handling of the work. A rapid sanitary survey should be made of each district, taking note of cases of sickness, insanitary conditions, rat mortality and prevalence, and the method of disposal of garbage. Daily reports of this work should be made to the central headquarters.

An indispensable adjunct of such an organization is the bacteriologic laboratory where all diagnoses should be verified, by appropriate means, and to which all rats and pathologic specimens should be sent for examination. A systematic bacteriologic examination of rats collected from all sections of the city should be carried out. Certain entomologic studies, more particularly in reference to the *Siphonaptera*, are also of interest.

Another important consideration—one most necessary in America—is legislation drafted especially to meet the extraordinary conditions existing in a plague-infected community. Epidemic outbreaks are of rare occurrence in this country, and, as a rule, no provision has been made in our laws, either state or municipal, for grave emergencies of this class. It will be necessary at the outset to draft a sanitary law, present it to the municipal council and request immediate action thereon.

If immediate and satisfactory legislation is secured, there is still another serious obstacle to be met, namely, the opposition of the people. This is always present, in some degree, in all commercial centers. If business has been seriously disturbed by the occurrence of panics, the local feeling may assume a very threatening tone. I recall an incident that occurred in the city of New Orleans where, during an epidemic of yellow fever, a physician was arrested and taken before a police justice for fumigating an infected residence.

The foregoing facts are related merely to emphasize the need of legal support and the importance of that other necessary feature of a successful campaign—the education of the public. The platform, press, pulpit and public schools should be utilized to place before the public the dangers of the situation. The story should be told in simple, forceful language in order that it may reach the understanding of all classes of citizens.

In the event that the press is lukewarm or hostile, there is no quicker or more satisfactory way of reaching the masses than through the civic bodies and women's clubs. Without the aid of the Citizen's Health Committee the San Francisco campaign would have dragged miserably at the cost of many valuable lives. No amount of education, however, will do away with the prejudices of some people. This is evidenced by the growing opposition to vaccination. Public education is hard work, and those who attempt it must be content to receive more "kicks than ha' pence." Self-control under the undeserved abuse of a hostile newspaper is, in my opinion, one of the essential qualifications of a good leader.

With such an organization it will be possible to rid a city of plague infection in a short time by the systematic destruction of rats. The most satisfactory method of exterminating them is by the employment of traps and poisons on a large scale. These measures should be supplemented by a simultaneous attack on the rats' food-supply and habitations. All edible refuse, or rat-pabulum, should be collected daily in metal receptacles and burned; the main harboring places should be sought out under wooden floors, in feed stables, granaries and warehouses, and destroyed. If these are made rat-proof, wherever practicable, by concreting the ground areas and side walls, and by screening all apertures near the ground level, rats will be deprived of their breeding-places.

The means above suggested will suffice to keep the rat population of the cities at a safe minimum. In centers where no such precautions are being taken every effort should be made to prevent the introduction of infected rats or squirrels and the parasites from these.

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

As to personal prophylaxis, it may be said that haffkinization or immunization has never been tried on a large scale in this country. In view of the brief immunity conferred (six months), and the personal discomfort which at times follows its use, it is not believed that the measure will ever become popular in our western civilization. The advisability of immunization for persons about to enter a plague-stricken city cannot be questioned, and the same applies to persons who are employed in antiplague measures. Yersin and Haffkine vaccines have both been used by us in San Francisco for the latter purpose. Vaccination, however, is not to be recommended as an eradicative measure.

POST-EPIDEMIC MEASURES

Of great importance in this connection is to know exactly when to discontinue the eradicative work. Antiplague operations require enormous financial outlays, and the municipal and state authorities will want to cut down appropriations at the very first indication that the epidemic is under control. What sign or indication, then, should govern our action in this matter?

The disappearance of human plague is not a safe criterion, nor is the failure to find infected rats to be depended on as a safe guide. It is safe to predict that the rat population will return in a short time, and if there is a vestige of the infection left it will light up again when the necessary combination of factors have ben restored.

It can be laid down as a universal standard that a certain amount of the work should be continued almost indefinitely after the last infected rat has been found. As a matter of fact, the enforcement of the building ordinances, and the special garbage regulations, must be made a permanent obligation on the city. These laws make for permanent civic immunity by building the rat out of existence. It will be necessary also to continue the work of rat extermination, on a somewhat smaller scale, by means of traps and poisons. The importance of keeping the rat population down to the minimum at such times, especially in certain threatened districts, cannot be too strongly emphasized.

Of interest in this connection is an examination of the records of the numbers of rats caught by months from September, 1907, to April, 1911, in San Francisco. The maximum catch was reached in the fall and winter of 1907. After that, although more rat catchers were employed, and a greater number of traps set daily, the catch diminished until a fixed monthly rate (index) was established. This indicates clearly if it indicates anything that a rat population can be controlled to a certain extent by appropriate means. Rat-proofing, however, is the most important single measure in the control of plague. The city which demands of its builders the rat-proofing of all buildings with concrete is insuring itself against a disastrous outbreak at some future day.

PLAGUE AS IT AFFECTS RURAL SANITATION IN CALIFORNIA

On the discovery of the existence of plague infection among the ground squirrels (*Citellus beecheyi*) of Contra Costa County, Cal., in the fall of 1908, it was realized at once that a serious feature had been added to the plague situation on the Pacific Coast. The investigations which were made then, and which have been carried to completion in the past two years, have confirmed that opinion. In view of the threatening possibilities, as above outlined, the surgeon-general authorized an ample allotment of the public health fund for the work.

The Pacific states, according to Merriam of the Geological Survey, are overrun with this and allied species of rodents, their ranges being continuous throughout the central and eastern portions of California. All states in which rodents are permitted to thrive unmolested should be regarded as infectible territory. The collection and bacteriologic examination of squirrels received from thirty-six counties showed that the infection was widespread.

It was long held by bacteriologists that the continued prevalence of plague in a locality (endemic) was due to the saprophytic power of the organism (*B. pestis*) which enabled it to live for long periods in soil and other inert material. The work of the Indian Plague Commission (1905), and other observers, directed the attention of the scientific world to a living intermediary (the rat) and this cleared up what had been a mystery for centuries. The finding of epizootic plague among the California ground squirrels accounts for the endemicity of the disease in this country.

Prevention of Spread from Rural to Urban Rodents.—The epizootic at present is limited to the former and should be eradicated before reinfection of the latter takes place. This is to be accomplished by carrying out the following measures:

A. Prevention of communication and the interchange of ectoparasites between the two by the creation and maintenance of rodent-free zones around the centers of population. This has been done at federal expense for the cities of San Francisco, Oakland, Alameda, Berkeley and Richmond.

B. Prohibition of transportation or traffic in rodents from one section to another by the application of state and municipal regulations. The California State Board of Health issued regulations against this practice as early as 1908.

Prevention of a Further Spread Among Rural Rodents.—This measure will afford protection to the adjacent states, Nevada, Oregon, Arizona and the Republic of Mexico which contain extensive infectible areas. Such measures should include the following:

A. Destruction of known enzootic foci. Extensive and valuable work of this character is being carried out under the direction of this Service in the ten infected counties.

B. General rodent destruction. This is to be taken up and carried on systematically and continuously in broad zones around the present infected areas, the idea being to limit the advance by breaking the chain, and to reduce the number of carriers (susceptible animals) so that if infection were introduced no wide-spread dissemination could ensue. It is an enterprise of great magnitude, as to cost and time, and can only be successfully managed by the adoption of a cooperative plan which must have the support of the individual farmers and county officials.

General extermination should be instituted as a systematic and continuous prophylactic measures in all Pacific and Mississippi Valley states. Interstate regulations should be so formulated as to prevent traffic in rodents from one to another except for scientific purposes. If not prohibited, it should be regulated and subjected to inspection under the most rigid precautions.

THE PREVENTION OF SPREAD BEYOND THE SEAS

Plague follows almost exclusively the lines of maritime commerce, and with but few exceptions the incidence of the disease is limited to the coast. The infection is conveyed to the shore, as a rule, by rats from infected ports, and the resulting rat mortality occurs first on the water front. As regards the source of rat supply, other than the natural local increase, it can be definitely stated that many rats come ashore from vessels engaged in the foreign and domestic trades.

Port regulations with regard to rat-guards (funnels) on hawsers and lines, as well as to fenders and gang planks are seldom effective. The funnels are generally too small, and not infrequently they are carelessly placed on mooring lines. It may be inferred from the foregoing that additional precautions should be taken to guard against rat infestations from abroad. This is undoubtedly necessary with regard to vessels coming from infected ports.

So important is this feature in the system of control herein advocated that mention should be made of the classification of ships as laid down by the Paris convention (1903), especially as it relates to the *indemne* vessel. Have events justified the exemption of vessels coming from plague-infected ports from the process of elimination of rats prior to entry? In answer to this question it can be stated that there are many quarantine officers in this country who believe that the *indemne* vessel should not be admitted to free pratique without first undergoing fumigation. The application of this measure is particularly indicated in instances in which vessels have embarked steerage passengers and cargo at an infected port. Exceptions may be made of vessels which have complied with all the quarantine laws and regulations of the United States for foreign ports.

Pandemics can be dealt with only through international regulations as follows:

1. The periodical fumigation of vessels to kill rats.
2. A medical surveillance of outgoing passenger and freight traffic at badly infected ports.
3. The appointment of an international commission to investigate and determine the location and extent of the endemic or enzootic centers, with authority to formulate plans for their eradication.
4. International notification of both epidemic and epizootic prevalence.

ABSTRACT OF DISCUSSION

ON PAPER AND REPORT OF DRS. BLUE, SNOW AND HEG

Dr. George E. Abbott, Pasadena, Cal.: In what I am about to say I do not wish to be considered as being opposed to the extermination of squirrels; on the contrary, I am most decidedly in favor of it. At the same time, however, I fear our present policy is prohibitory of success. I understand that there is an ordinance about to be enforced whereby the owners of land are to be made responsible for any rodents found on their premises. The extermination of even a small percentage of squirrels would, in many places, cost from five to ten times the value of the land per acre. Moreover, in many instances, the government land is the *greatest sinner*. This measure is manifestly unfair to the farmer. The most that can be asked the farmer is to do the work, while the state or government provides the material. Moreover, it is the towns-people who are crying for protection against the plague and its contagion. Let the cities, state and government furnish the weapons of war and then demand of the farmer the labor of exterminating the rodents, which will, at one and the same time, protect the people and the crops from destruction. My belief is that such measures would not have to be enforced, but would be gladly adopted by all.

Dr. J. W. Kerr, Washington, D. C.: As a colleague of Dr. Blue I am naturally very much interested in his work. It is not my intention, however, to discuss it, but rather to mention briefly some measures that have been taken by the federal government for the prevention of the introduction of plague from abroad.

The Quarantine Act of Feb. 15, 1893, authorizes the President to detail officers of the Public Health and Marine-Hospital Service for duty at infected ports abroad for the purpose of supervising American shipping to prevent the introduction of exotic diseases. It was my privilege, after the beginning of the outbreak of plague in San Francisco in 1900, to be etailed to the port of Hongkong, China. At that time the isease was very prevalent there, and had been prevailing for bout five or six years. The problem of the protection of American shipping was, accordingly, a difficult one, particurly on account of the close proximity of Manila to the port Hongkong. Cognizance had to be taken of the passengers, rgoes and crews of all ships. Every passenger leaving the port of Hongkong (and this is true of other infected ports in the Orient) was required to undergo inspection prior to embarkation. Foreign products, and particularly Chinese food-products, were inspected, not only just prior to loading, but where the food was stored, and also in the localities from which they came. As a result it was found that a very small amount of this kind of food was at all liable to carry plague infection, and probably never had carried it.

The most important means of protection against plague is preventing rats from gaining access to the ships while in harbor. It was the practice to disinfect ships periodically to kill rats; and this, in the case of trans-Pacific ships, was done every third voyage. By this means the rat population aboard ships was kept at a low ebb and greater protection was afforded in that way than any other. Since that time there has been an international agreement, adhered to by a number of foreign countries, as well as our own, for the prevention of the spread of plague, cholera and yellow fever in international commerce.

Dr. Blue referred to the necessity of the periodical disinfection of ships to free them from rodents. This has been brought to the attention of the permanent international committee, which has control of the International Office of Hygiene established at Paris in accordance with the International Sanitary Treaty of 1903. Furthermore, our quarantine regulations require the periodical disinfection of ships to kill rats at least once in six months; that is, any ship that has within a recent time been in an infected port. Dr. Blue referred to indemne ships as being subject to disinfection. An indemne ship is one which, although coming from an infected port, has had neither death nor case aboard, and these ships are practically always disinfected on arrival in our ports to kill rats.

With reference to the methods in a city to eradicate plague, I want to mention one measure that was adopted in Hongkong, the depopulation of infected areas. This was practically the only way that some local outbreaks there could be stopped.

A method of determining the extent of infected areas has been outlined by Dr. Heiser, Director of Health of the Philippine Islands, by which his rat-catchers catch rats along radiating lines toward the known infected center. These rats are examined in the laboratory and the circumference of the infected area is thus outlined. Since the above system was adopted plague has disappeared from Manila, in which city the disease has not prevailed for several years.

Dr. Elmer E. Heg, Seattle, Wash.: The fact that plague has prevailed only on the Pacific Coast in this country has had a tendency to cause our eastern brothers to think that this is a western subject only. If they would stop to think that London and Edinburgh and European ports have been infected, they would realize that we have a problem that should be studied by the eastern men interested in public health as well as by the western men; and it is only when they get an epidemic, or get a case of plague, that they will realize what they are up against. When they first had the plague in California, I was interested, but not materially so. I was interested as our eastern men are now. It was when we got the plague in Seattle that it became a different subject, and I have realized, for the past four years, what it is to have plague in one's own state. The committee, of which I am one, recommended that the extermination of rodents be continued indefinitely. This seems, perhaps, rather a strange, or rather a rigorous, recommendation. The fact is that the next to the last plague rat found in Seattle was found in September, 1908; and although from four or five hundred to a thousand rats daily were examined from that time on, no more plague rats were found until February, 1910, a year and a half after the last previous plague rat was caught. Now, whether this was a hold-over or whether it was a new infection, I cannot tell you. If it was a new infection, it must have come from somewhere else; and other cities are just as apt to get it as we were. We certainly had carefully examined the city for rats; and yet one appeared after an interval of one and one-half years.

The cities should protect themselves by their building ordinances and by a systematic examination of rats. Not only will it help them in controlling plague, but the commercial benefits will pay. The losses to merchants through rats are many times more than the cost of extermination or protection. Since we started in Seattle to exterminate rats we have gotten the different merchants interested and they keep it up right along, in conjunction with the city. It pays them to do it. And when you can appeal to a merchant and show him that his loss in merchandise is greater through the rat than the cost of keeping them out he becomes a sanitary agent; but you have got to show him that there is money in it.

One of the speakers mentioned the fact that the farmers would eradicate squirrels for the loss of crops but not to protect the cities. That illustrates the exact point. Only those who are interested in public health are willing to do anything unless there is a dollar in it; but the eradication of rats, and of ground-squirrels also, is certainly a commercial proposition, just as well as a sanitary proposition.

Dr. N. K. Foster, Oakland, Cal.: For a good many years Dr. Blue has stood by California and fought that disease pretty nearly to a finish; and we fully appreciate him in that part of the state. If our editors, and some of our public men, had been educated in the ordinary principles of truth, we would not have had the trouble in California that we did. In the first place, educate the people—and the children, beginning at the bottom—so that they will understand that plague is simply a disease that can be handled just as well as any other; that there is no especial danger in it if we handle it scientifically; teach them to meet the fact, and if plague breaks out that we are going to eradicate it, and that they have got to help to do it; but teach the children in the primary grades, in the grammar grades, and in the high-school grades, and up into the universities, just what it is and how to handle it. In California we are adopting at the present time a new book on physiology, hygiene and sanitation, and we are trying to get, and I think will get, a chapter on plague in that book. I would really advise, in conjunction with Dr. Heg, that you eastern men and women take up this question and study it carefully; for you cannot tell how quickly it will come to your doors. I have believed ever since it broke out here, that some time you will have it. I hope you will not, for, as Dr. Heg says, it is a very different thing when you get it at your own door and have to fight it, from when it is away off in California or Washington. The next thing that I would emphasize is to have every one rat-proof his own building. It can be cheaply done. Simply have the basement of your house of other building spread with concrete so that the rat cannot get through. If he gets into your house, let it be through the same opening that you go and you will be practically safe.

REPORT OF COMMITTEE ON METHODS FOR THE CONTROL OF EPIDEMIC POLIOMYELITIS *

Within the last two years the attention of the medical profession has been strongly directed to the prevention of poliomyelitis, first, because of its increasing prevalence in epidemic form and the serious nature of its after-effects; and, secondly, because it has been shown to be an infectious disease due to a filterable virus, probably a specific microorganism, from which the inference has been very naturally drawn that it is necessarily preventable.

As regards its prevalence, there can be no doubt that it has very greatly increased in recent years, especially in the United States. During the year 1909 not less than 2,500 cases were reported as occurring in epidemics in the United States. During that year 539 deaths, indicating probably not less than 5,000 cases, were reported from the registration area comprising 55 per cent. of the population of the United States.

For the year 1910, 5,093 cases and 825 deaths have been reported to the Surgeon-General of the Public Health and Marine-Hospital Service from thirty-one states, the District of Columbia and Hawaii. It can hardly be doubted that these statistics give a very imperfect and much too low estimate of the prevalence of the disease. Granting, however, a prevalence several times as great as reported, a mortality of 5 to 20 per cent., and permanent disability in perhaps 75 per cent. of the survivors, still the magnitude of the public health problem involved has undoubtedly been greatly exaggerated. Compared with the ravages of tuberculosis, pneumonia, typhoid fever, infantile diarrhea, scarlet fever, diphtheria, measles, whooping-cough, and even of such a comparatively rare disease as cerebrospinal fever, the havoc wrought by poliomyelitis on the country at large, while not negligible, is yet very small.

As regards its preventability also there has seemingly been some hasty and unwarranted optimism. Inferences drawn from laboratory studies of experimental poliomyelitis have been applied to the disease as occurring in nature with too little consideration of the vast differences between laboratory and natural conditions. While laboratory experiments have, it is true, furnished indications not only that poliomyelitis is preventable, but also to some extent of the methods by which its prevention may be accomplished, the final proof of preventability, namely, demonstrable control of the disease, is still lacking.

In the absence of data as to the actual efficacy of preventive measures, the present report must necessarily be drawn up on theoretical grounds, from data which are, in some essential respects, deficient. The facts needed for the deduction of effective preventive measures for an infectious disease include the following or a close approximation to them:

1. A knowledge of the specific causative agent—its habitat, the conditions necessary for its life and propagation, and the agencies by which it may be destroyed.
2. A knowledge of the means by which the causative agent may be and most commonly is transmitted from its habitat to healthy persons, and the avenue by which it gains entrance to the human body.
3. A knowledge of the conditions which constitute susceptibility to infection by the agent when it has been introduced into the body.

The knowledge of these facts may be effectually applied to the prevention of the disease; provided that the causative agent can be controlled or destroyed in some part of its life history, or that immunity to the infection can be established by measures of practical application.

As a preliminary to the presentation of any recommendations regarding methods for the control of poliomyelitis, it seems necessary to summarize as briefly as possible the essential facts known concerning its etiology and dissemination.

I. EXPERIMENTAL STUDIES

1. The Specific Causative Agent or Virus.—The successful transmission of poliomyelitis from man to monkeys, and from monkey to monkey, has demonstrated that the disease is due to a specific virus which passes readily through a bacteria-proof filter. Several observers have reported the demonstration of minute bodies in the filtrate from emulsions of the cord of infected monkeys. Much larger bodies have been found by the Pennsylvania health authorities in the blood of infected persons and monkeys. It has not, however, been established that the bodies demonstrated either in the blood or in the filtrates are the causative organisms.

Although the virus has probably been cultivated on artificial media, such cultures offer no practical aid to its isolation or identification. Its recognition, therefore, depends solely on the characteristic effects produced in animals.

2. Habitat of the Virus.—The virus of poliomyelitis has been shown to be present in the following locations:

A. In man: In the spinal cord and bulb (and possibly in the spleen, blood and cerebrospinal fluid) of persons who have died during the acute stage of the infection.

B. In lower animals: In monkeys experimentally infected the virus has been found in the brain, spinal cord; mesenteric, axillary and salivary glands, and in the nasal and pharyngeal mucous membrane. It has been found in the blood and cerebrospinal fluid only in the early stages of infection, and apparently in great dilution. In the nasopharyngeal mucous membrane it has been found to persist for as long as five months after the acute stage of the infection.

Several observers claim to have reproduced the disease in rabbits by inoculation with human virus and to have propagated the infection thence to other rabbits and to monkeys. Some doubt, however, remains concerning the transmission of poliomyelitis to rabbits. The majority of observers have found them insusceptible, and those who have reported success in transmitting the disease have failed to find characteristic histologic lesions. With the exception of these somewhat doubtful demonstrations in rabbits, the virus has not been found in lower animals other than experimentally infected monkeys. Inoculations of other varieties of laboratory and domestic animals have given only negative results. None of these animals (guinea-pigs, rats, mice, dogs, cats, sheep, goats, hogs, horses, chickens and pigeons) has so far been found susceptible to the disease. Also, pathologic and experimental studies on mammals and fowls suffering from paralysis similar to human poliomyelitis have failed to establish any etiologic relation between such diseases and poliomyelitis.

C. Outside the animal body: The virus has never been found outside the animal body. Its demonstration in the nasopharyngeal mucous membrane and salivary glands of experimentally infected monkeys has led to the inference that the nasal and buccal secretions contain the virus. However, experiments made to demonstrate the infectiveness of these secretions, as well as of the urine and feces of infected persons and monkeys, have been uniformly unsuccessful.

3. Viability of the Virus.—Studies on viability have been necessarily confined to animal tissues containing the virus. Under these conditions the virus has been found easily destroyed by heat (45 to 50 C.) and by comparatively weak disinfectants. It has been found resistant to low temperatures, desiccation and the action of glycerin.

4. Vehicles of Transmission and Avenues of Infection.—Since the virus has been found only in the tissues of naturally infected persons and experimentally infected animals (of a plied with all the quarantine laws and regulations of the United States for foreign ports.

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Pandemics can be dealt with only through international regulations as follows:

1. The periodical fumigation of vessels to kill rats.
2. A medical surveillance of outgoing passenger and freight traffic at badly infected ports.
3. The appointment of an international commission to investigate and determine the location and extent of the endemic or enzootic centers, with authority to formulate plans for their eradication.
4. International notification of both epidemic and epizootic prevalence.

ABSTRACT OF DISCUSSION

ON PAPER AND REPORT OF DRS. BLUE, SNOW AND HEG

Dr. George E. Abbott, Pasadena, Cal.: In what I am about to say I do not wish to be considered as being opposed to the extermination of squirrels; on the contrary, I am most decidedly in favor of it. At the same time, however, I fear our present policy is prohibitory of success. Simply have the basement of your house of other building spread with concrete so that the rat cannot get through. If he gets into your house, let it be through the same opening that you go and you will be practically safe.

REPORT OF COMMITTEE ON METHODS FOR THE CONTROL OF EPIDEMIC POLIOMYELITIS *

Within the last two years the attention of the medical profession has been strongly directed to the prevention of poliomyelitis, first, because of its increasing prevalence in epidemic form and the serious nature of its after-effects; and, secondly, because it has been shown to be an infectious disease due to a filterable virus, probably a specific microorganism, from which the inference has been very naturally drawn that it is necessarily preventable.

As regards its prevalence, there can be no doubt that it has very greatly increased in recent years, especially in the United States. During the year 1909 not less than 2,500 cases were reported as occurring in epidemics in the United States. During that year 539 dea[illegible] not less than 5,000 cases, were reporte[illegible] area comprising 55 per cent. of the [illegible] States.

For the year 1910, 5,093 cases and 825 deaths have been reported to the Surgeon-General of the Public Health and Marine-Hospital Service from thirty-one states, the District of Columbia and Hawaii. It can hardly be doubted that these statistics give a very imperfect and much too low estimate of the prevalence of the disease. Granting, however, a prevalence several times as great as reported, a mortality of 5 to 20 per cent., and permanent disability in perhaps 75 per cent. of the survivors, still the magnitude of the public health problem involved has undoubtedly been greatly exaggerated. Compared with the ravages of tuberculosis, pneumonia, typhoid fever, infantile diarrhea, scarlet fever, diphtheria, measles, whooping-cough, and even of such a comparatively rare disease as cerebrospinal fever, the havoc wrought by poliomyelitis on the country at large, while not negligible, is yet very small.

As regards its preventability also there has seemingly been some hasty and unwarranted optimism. Inferences drawn from laboratory studies of experimental poliomyelitis have been applied to the disease as occurring in nature with too little consideration of the vast differences between laboratory and natural conditions. While laboratory experiments have, it is true, furnished indications not only that poliomyelitis is preventable, but also to some extent of the methods by which its prevention may be accomplished, the final proof of preventability, namely, demonstrable control of the disease, is still lacking.

In the absence of data as to the actual efficacy of preventive measures, the present report must necessarily be drawn up on theoretical grounds, from data which are, in some essential respects, deficient. The facts needed for the deduction of effective preventive measures for an infectious disease include the following or a close approximation to them:

1. A knowledge of the specific causative agent—its habitat, the conditions necessary for its life and propagation, and the agencies by which it may be destroyed.
2. A knowledge of the means by which the causative agent may be and most commonly is transmitted from its habitat to healthy persons, and the avenue by which it gains entrance to the human body.
3. A knowledge of the conditions which constitute susceptibility to infection by the agent when it has been introduced into the body.

The knowledge of these facts may be effectually applied to the prevention of the disease, provided that the causative agent can be controlled or destroyed in some part of its life history, or that immunity to the infection can be established by measures of practical application.

As a preliminary to the presentation of any recommendations regarding methods for the control of poliomyelitis, it seems necessary to summarize as briefly as possible the essential facts known concerning its etiology and dissemination.

I. EXPERIMENTAL STUDIES

1. The Specific Causative Agent or Virus.—The successful transmission of poliomyelitis from man to monkeys, and from monkey to monkey, has demonstrated that the disease is due to a specific virus which passes readily through a bacteria-proof filter. Several observers have reported the demonstration of minute bodies in the filtrate from emulsions of the cord of infected monkeys. Much larger bodies have been found by the Pennsylvania health authorities in the blood of infected persons and monkeys. It has not, however, been established that the bodies demonstrated either in the blood or in the filtrates are the causative organisms.

Although the virus has probably been cultivated on artificial media, such cultures offer no practical aid to its isolation or identification. Its recognition, therefore, depends solely on the characteristic effects produced in animals.

2. Habitat of the Virus.—The virus of poliomyelitis has been shown to be present in the following locations:

A. In man: In the spinal cord and bulb (and possibly in the spleen, blood and cerebrospinal fluid) of persons who have died during the acute stage of the infection.

B. In lower animals: In monkeys experimentally infected the virus has been found in the brain, spinal cord; mesenteric, axillary and salivary glands, and in the nasal and pharyngeal mucous membrane. It has been found in the blood and cerebrospinal fluid only in the early stages of infection; and apparently in great dilution. In the nasopharyngeal mucous membrane it has been found to persist for as long as five months after the acute stage of the infection.

Several observers claim to have reproduced the disease in rabbits by inoculation with human virus and to have propagated the infection thence to other rabbits and to monkeys. Some doubt, however, remains concerning the transmission of poliomyelitis to rabbits. The majority of observers have found them insusceptible, and those who have reported success in transmitting the disease have failed to find characteristic histologic lesions. With the exception of these somewhat doubtful demonstrations in rabbits, the virus has not been found in lower animals other than experimentally infected monkeys. Inoculations of other varieties of laboratory and domestic animals have given only negative results. None of these animals (guinea-pigs, rats, mice, dogs, cats, sheep, goats, hogs, horses, chickens and pigeons) has so far been found susceptible to the disease. Also, pathologic and experimental studies on mammals and fowls suffering from paralysis similar to human poliomyelitis have failed to establish any etiologic relation between such diseases and poliomyelitis.

C. Outside the animal body: The virus has never been found outside the animal body. Its demonstration in the nasopharyngeal mucous membrane and salivary glands of experimentally infected monkeys has led to the inference that the nasal and buccal secretions contain the virus. However, experiments made to demonstrate the infectiveness of these secretions, as well as of the urine and feces of infected persons and monkeys, have been uniformly unsuccessful.

3. Viability of the Virus.—Studies on viability have been necessarily confined to animal tissues containing the virus. Under these conditions the virus has been found easily destroyed by heat (45 to 50 C.) and by comparatively weak disinfectants. It has been found resistant to low temperatures, desiccation and the action of glycerin.

4. Vehicles of Transmission and Avenues of Infection.—Since the virus has been found only in the tissues of naturally infected persons and experimentally infected animals (of a species which cannot be considered of importance in its natural transmission), the carriers of the infection outside the human body can only be inferred from the biology of the virus and the epidemiology of the disease. Laboratory studies so far indicate (although they do not prove) that the virus has no natural animal host except man, and that its viability outside the human body is short. To that extent they indicate direct transmission from person to person.

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Possible avenues of infection experimentally demonstrated are numerous. Monkeys may be infected by inoculation into the brain, cerebrospinal canal, peripheral nerves, vascular system, peritoneal cavity, anterior chamber of the eye, or subcutaneous tissue. They have been infected through the digestive tract by introducing massive doses of the virus into the stomach or intestines, peristalsis being retarded by the administration of opium. Through the respiratory tract infection has been caused by rubbing the virus into the scarified nasal mucous membrane, and in one instance through the intact nasopharyngeal mucosa.

5. Susceptibility.—Laboratory experiments have thrown practically no light on the conditions determining natural susceptibility or immunity to the infection. Monkeys are almost uniformly susceptible to artificial infection by inoculation. They have not, however, been known to contract the disease spontaneously, although in several laboratories considerable numbers of them have been kept in contact with artificially infected monkeys. Acquired immunity, both active and passive, has been shown; but no practical means of immunizing persons has been developed. The susceptibility of monkeys may be diminished by the administration of hexamethylenamin, and it is reasonable to infer that this may apply also to human beings.

II. EPIDEMIOLOGIC STUDIES

Satisfactory epidemiologic data from which to draw inferences as to the transmission of poliomyelitis are scant. Such data are lacking, both in extensiveness, failing to give an accurate idea of the prevalence and distribution of endemic and epidemic cases, and also in accuracy of detail, failing to give full enough information concerning the cases studied.

The following important facts are, however, pretty well established:

1. Geographic Distribution.—Epidemics have occurred over a very wide, not definitely limited area, including all sections of the United States, various parts of Canada and the West Indies, most if not all the European countries, Australia and Micronesia. Sporadic cases are of even wider distribution.

The distribution of epidemic areas is quite peculiar, showing no constant definite relation to previous epidemic foci, to density of population or to the amount of communication by travel. In general, it is true that densely populated cities suffer relatively less than rural districts. Epidemics have sometimes appeared to be confined to certain water-courses, and investigations in Pennsylvania seem to show a greater prevalence of the disease over old formations, poorly drained, than over gravel formations, but no constant relation has been shown to exist between topographic or telluric conditions and the occurrence of epidemics.

2. Seasonal Prevalence.—In the northern hemisphere the disease is markedly more prevalent during the summer and fall months; in the southern hemisphere during the winter and spring. In general, hot, dry weather seems to be one of the conditions most favorable for its spread.

3. Incidence of Disease Among Population.—The total attack-rate in the population of any considerable area is always small. It is seldom that more than one to ten per thousand are attacked, and even this latter rate is not often reached in a population of more than a few thousand. The greatest incidence, both actual and relative, is in the first decade of life, usually from the second to the fifth year. The proportion of adults to children attacked varies greatly, however, in different epidemics. More males than females are attacked. Such statistics as are available indicate that during the first decade of life males and females are attacked at approximately the same rate, but that in later life males are attacked much more frequently.

4. Origin and Means of Dissemination of Epidemics.—None of the epidemiologic investigations undertaken can be said to have shown the origin and means of dissemination of epidemics. Practically all observers have failed to find any relation between the spread of the disease and certain factors commonly operative in the dissemination of many infectious diseases, namely, food and water-supplies, crowding and insanitary environment.

Regarding other factors, findings have been various and opinions divergent.

A. Contagiousness.—Direct Transmission from Person to Person: The most comprehensive and in many respects most reliable information on this point is derived from a study of the attack-rate in persons known to have been in intimate contact with recognized acute cases. A study of multiple cases in families, institutions and schools shows that only a small proportion of persons known to have been in such contact have subsequently developed the disease. Therefore, if we limit recognized cases to persons with *actual paralysis*, it must be admitted that the disease is usually very slightly contagious as compared with scarlet fever, measles, diphtheria or typhoid fever.

On the other hand, studies of small outbreaks have not infrequently shown indications of direct transmission, and occasionally an apparently high degree of contagion. This is especially true in instances in which abortive cases have been included in the epidemiologic studies. Studies of this kind are, however, too few to furnish a basis for general conclusions and to eliminate the error introduced by personal bias in the inclusion of abortive cases.

For the present it may be concluded that few clinically recognized cases can be traced to contact with previous clinically recognized cases. If the disease is transmitted by direct contact, paralytic cases must be a small factor in its dissemination.

Factors of possibly greater importance are:

1. Abortive and Clinically Unrecognized Cases: The existence of such cases, often so mild as to be ambulant, has been inferred on clinical evidence and confirmed by the demonstration of apparently specific microbicidal properties in the blood-serum of a number of suspected cases.

2. Carriers: The experiments of Osgood and Lucas, and of Flexner and Clark, demonstrating that the virus may persist in the nasal mucous membrane of artificially infected monkeys for several weeks—in one instance as long as five months—indicate the probable existence of human chronic (convalescent) carriers. The existence of healthy carriers—persons in whose bodies the virus multiplies without causing infection—can only be surmised at present. Numerous cases are cited in which infection has apparently been conveyed by a healthy intermediate person. The epidemiology of cerebrospinal meningitis has been interpreted as offering an analogy to this method of transmission, furnishing an example of a disease spread by healthy carriers, whose number has in many instances appeared to be greater than the number of persons actually suffering from the disease.

The presumption of healthy carriers, namely, persons harboring the germs but not suffering from the infection, carries with it as a necessary corollary individual variations in susceptibility. The existence of abortive cases, while not proving this assumption, tends to confirm it. The uneven distribution of the disease in different age groups and between males and females, and also its seasonal distribution, suggest variations in susceptibility as their explanation. To offer variations in susceptibility as an explanation of the irregular incidence of the disease is, however, begging the question unless some satisfactory demonstration of such variations can be offered at the same time. It is reasoning in a circle to advance a variable factor of susceptibility in explanation of the irregular incidence of a disease and then to advance the irregular incidence as a proof of variable susceptibility. Satisfactory proof that susceptibility to poliomyelitis varies to any considerable extent is lacking. While, therefore, it is reasonable to suppose that the element of individual susceptibility is a factor in the epidemiology of this disease, its importance is as yet undetermined.

The digestive tract as the avenue of infection is suggested by several facts, namely, the seasonal prevalence, the greater incidence in childhood and the early and almost constant occurrence of gastro-intestinal symptoms in the acute stage.

On the theory of poliomyelitis being directly transmissible from person to person, it is difficult to offer a satisfactory explanation of its uneven distribution in relation to density of population and travel.

B. Theories explaining the dissemination of poliomyelitis by agencies other than direct transmission from person to person are worthy of careful consideration. Of these theories, the one which appears to the committee to have the best basis of fact assumes that the disease is transmitted from lower animals to man. This theory is supported by the occurrence among domestic animals (horses, dogs, cats, sheep, hogs, cattle and poultry) of paralytic diseases clinically resembling acute anterior poliomyelitis. Experimental studies have so far failed to show that such diseases are in any way etiologically allied to the human disease and have, on the other hand, shown that these animals are insusceptible to inoculation with the virus derived from human cases.

The distribution of paralytic diseases in animals in relation to human poliomyelitis has not been determined with all desirable accuracy, and it is therefore impossible to state at present how closely it corresponds to the distribution of human poliomyelitis.

It has been suggested that the disease is conveyed from horses to man by dust from barnyards and streets. The evidence in favor of this theory is as follows:

1. The greater frequency of the disease in the country and in small villages than in more densely populated cities where, as a rule, streets are better paved and less dusty.

2. Its greatest prevalence during the season when dust is generally most prevalent.

3. Its greatest prevalence among children at the age when they commonly play in the dust, and its greater prevalence among adult males; who are relatively more out of doors than in females who are more intimately exposed to contact with the sick.

4. The distribution of cases in several towns on the more dusty streets; and the cessation of several epidemics after sprinkling the streets.

The probability of some insect being a factor in the transmission of poliomyelitis has been suggested by several epidemiologic observations, namely:

1. A seasonal prevalence corresponding to the maximum prevalence and activity of many varieties of insects.

2. The irregular distribution of epidemics. Outbreaks have occurred simultaneously or consecutively in localities separated by wide, often densely populated and much-traveled areas in which the disease has not been epidemic.

3. The relatively greater prevalence of the disease in rural communities and in small towns than in large densely populated cities, where the opportunities for the spread of diseases transmissible directly from person to person are generally greater.

4. The absence, in epidemic areas, of any constant and obvious relation between cases in regard to proximity, intercommunication or exposure to readily discernible common sources of infection.

Such peculiarities in the epidemiology of poliomyelitis have been thought by some to be most readily explained by the assumption that some insect, showing corresponding peculiarities in its distribution and activities is a necessary factor in the spread of the disease. Dr. Conn of the Connecticut State Board of Health has recently suggested the flea as a probable carrier of the infection. It is doubtful, however, whether all the facts known concerning the biology of the flea are in accord with this hypothesis.

III. RECOMMENDATIONS

The committee recommends, as the most important step toward the prevention of poliomyelitis, further studies of its means of transmission and of the factors of immunity.

While it is hoped that experimental studies on the transmission of the disease will be continued and will be as productive of results in the future as in the past, neither recommendations nor prophecies in this regard come within the scope of this report.

The collection of data which it is believed will greatly enlighten the question, and the collection of which is quite practicable, is recommended as follows:

1. Prevalence.—It is obviously of the greatest epidemiologic importance to determine as accurately as possible the prevalence and distribution of the disease. This can be accomplished most efficiently and thoroughly through state and municipal health organizations, by requiring that poliomyelitis be reported as an infectious disease. In the absence of any definite diagnostic criterion except paralysis, reports could, for the present, be required of paralytic cases only. It is desirable, moreover, that morbidity and mortality statistics should, for the present, be based on definitely diagnosed paralytic cases. Abortive cases should be included wherever practicable in the statistics of the disease, but should be designated as such and tabulated separately.

2. Diagnosis.—Further and more detailed studies of the symptomatology and of the blood and cerebrospinal fluid of patients in the preparalytic stage and of suspected abortive cases are needed to establish a more definite standard of diagnosis. For collective studies of this kind local medical societies have opportunities which are rarely available to public health organizations.

3. Epidemiology.—In connection with the collection of morbidity reports, state and municipal health authorities can, by obtaining more detailed reports, collect data of considerable epidemiologic importance. Valuable studies based on data so collected have already been made by several state and city health organizations and by medical societies. The value of the data so collected would be much increased by greater uniformity in the methods of collecting them. The employment of a uniform blank for this purpose is recommended.

It is necessary, however, for a better understanding of the transmission of the disease, that such studies be supplemented by more detailed information, based on a systematic epidemiologic study of individual cases by competent epidemiologists. Studies of this nature have already been undertaken in several states and have resulted in the collection of the most thorough, instructive and satisfactory data so far available.

The objects of an intensive study should be to determine as accurately as possible:

1. Clinical types with special reference to early diagnosis with the aid of laboratory methods.

2. The actual prevalence of the disease in each community studied. This would necessitate an investigation not only of definite paralytic cases, but also of suspected abortive cases.

3. The distribution of cases and their relation to each other and to possible common causes. Among the etiologic factors other than direct contact which deserve especial study are: the prevalence of paralytic diseases among animals; meteorologic conditions, especially the prevalence of dust; immediate environmental conditions with special reference to crowding, sewage disposal and the presence of insects; food and water-supplies; the prevalence of other diseases.

Pending the results of further investigations, the committee recommends the following preventive measures based on the assumption that the disease is directly transmissible from person to person.

1. Isolation and screening of all patients known to have or suspected of having the disease. Since a positive diagnosis can be made only on the appearance of paralysis, which usually develops one to six days after the onset of febrile symptoms, and in abortive cases does not appear at all, isolation, to offer any hope of effectiveness, must be instituted on suspicion. Three weeks from onset is suggested as the period of isolation, although only a surmise can be made on this point.[1]

2. Disinfection of all discharges from patients, and of all articles used by them and their attendants.

3. Fumigation of the premises with formaldehyd on release from isolation.[2]

4. A quarantine of persons in contact with patients does not seem at present justifiable. It is recommended, however, that members of patients' families be excluded from schools during the period of the patients' isolation and during the possible incubation period of a new case; that is, for three weeks following the end of the last exposure to the (presumptively) contagious person.

5. For the protection of persons presumably exposed to infection, namely, those in contact with the sick and in communities where the disease is epidemic, the daily administration of hexamethylenamin seems to offer some hope of reducing susceptibility. It seems not unreasonable to suppose that susceptibility, especially of young children, may perhaps be further modified by preserving the gastro-intestinal tract in normal condition, by avoiding dietetic errors, by prompt attention to slight gastro-intestinal disturbances and by the avoidance of overexertion in hot weather. Rest, which seems to be an important therapeutic measure, may quite possibly have some prophylactic value.

The committee is unable to express any great confidence in the efficacy of the measures above outlined. Even granting that the disease is transmitted directly from person to person by infectious secretions, the difficulties in the way of its prevention are great.

It is often impossible to recognize even severe paralytic cases before the onset of paralysis, which may be several days after the onset of the disease. It is still more often impossible to recognize and isolate abortive cases, whose number may reasonably be supposed to be considerable. Chronic convalescent carriers, whose existence is probable, and healthy carriers, whose existence is not improbable, are not recognizable and hence cannot be controlled.

---

[1] In the opinion of one member of the committee (H. W. H.) a period of two weeks is sufficient to meet the situation as we understand it.

[2] In the opinion of one member of the committee (H. W. H.) terminal fumigation is unnecessary. In the present status of our knowledge concurrent disinfection, i. e., disinfection of the discharges of the nose and mouth, should be rigidly carried out.

Moreover, the disease is already wide-spread throughout the country, and experience with other infectious diseases has shown the difficulties which beset the eradication of a wide-spread endemic infectious disease by quarantine alone. Finally, it will be difficult to estimate the efficacy of preventive measures, since it is impossible to foretell the extent to which the disease is likely to spread in any community without the application of restrictive measures.

If, however, the above measures actually prevent even a small proportion of cases they are justified.

REPORT OF COMMITTEE ON CONTROL OF CONTAGION THROUGH PHYSICIANS AND NURSES*

The subject, "Control of Contagion Through Doctors and Nurses," might imply that these are the only agencies for combating contagious disease, which is not quite true, though health boards must primarily depend on these agencies for preventive work. Through their efforts and teaching many other agencies, such as clubs, church organizations, social centers, fraternal bodies, principals and teachers in schools, and parents, are made to cooperate in preventing the spread of contagion. Doctors and nurses, however, are the only agencies employed legally and under control of municipal authority.

To control contagion we must first know where contagion exists. It follows that there must be authority to compel physicians, parents and guardians to report to boards of health, all cases of contagious disease when found. This should include suspected cases of contagious diseases—these to be dealt with differently from actual cases as explained further on.

City ordinances should be comprehensive and yet explicit enough to make their enforcement easy. Loosely drawn ordinances invite legal resistance. In the absence of city ordinances, state health laws can be invoked. In the absence of ordinances or state health laws we can proceed under the general police power. Under police powers a board of health can take such measures as are necessary to protect the public health against epidemic diseases and such action will be sustained by public opinion and the courts.

In order to secure reports of contagious diseases, postal cards, on which is indicated the information desired by the department of health, should be furnished free to physicians (Form 1). The acute contagious diseases—small-pox, diphtheria, scarlet fever, measles and whooping-cough—should be reported by telephone and by postal card. Telephoning the report makes it possible to take action twenty-four hours earlier than if the case were reported by mail. The postal card, with the physician's signature, following the telephone report, is necessary for the record of the case.

Other reportable diseases may be reported by card only.

When a case of contagious disease is reported, an acknowledgment of receipt of the report should be sent to the person making the report, on one half of a double postal card (Form 2), the other half of the postal card to be torn off and returned to the department of health when the case is ready for termination.

The name and address of the reported patient are telephoned to the medical health officer in whose territory the case is found. He visits the patient and establishes quarantine. If no adequate quarantine can be established and maintained, the patient should be sent to a hospital for contagious diseases.

In cases of diphtheria, if the attending physician has not taken a culture from the throat, the health officer should take one. If the case proves to be bacteriologically and clinically not diphtheria, the attending physician receives notice from the department of health of the laboratory findings (Form 3), and a postal card enclosed on which he expresses his wish as to the early termination of the case (Postal Card Form 4). The health officer gives immunizing doses of antitoxin to other members of the family if the attending physician has not done so; gives oral instructions to the family and printed instructions as to the management of the case (Circular 1) to prevent the spread of contagion. A printed card of instructions is hung on the door of the patient's room (Circular Card Form 2). The medical health officer endeavors to place the patient in a room apart from other members of the household with a view of preventing other inmates of the house from contracting the disease. A warning card (Placard Form 1) should be placed on the front door, and a milkman's warning card on which are printed instructions to be followed by the milkman (Placard Form 2) is placed on the rear door. The medical health officer fills out a blank quarantine card (Form 5), giving information and instructions as to the quarantine requirements to the quarantine officer who follows him. This card is placed under the right upper corner of the front door warning card and a tack is driven through both. The medical health officer fills out and mails a postal card (Form 8), notifying school principal, Sunday-school superintendent and factories in the neighborhood, giving the location of the case. He then fills out his report blank (Form 9), giving detailed information as to the conditions and requirements of quarantine in the case and mails it to the department of health.

The following day a quarantine officer calls and secures the instruction card which was placed under the front door warning card by the medical health officer. This card informs him what the quarantine requirements are in the case. This officer visits the house daily, or as often as necessary, to see that the inmates are obeying the rules of quarantine. At each visit he fills out and sends to the department of health a report (Form 10). When the patient is well, the attending physician sends to the department his termination card (Postal Card Form 2). The medical health officer is then sent to take cultures from the throat and nose of the patient, and if found positive he waits three days and returns for another culture, and so continues until a culture shows negative, in which case he returns the following day and takes another culture and at the same time takes cultures from the throats of all contacts. If they all prove negative, he fills out blank (Form 11), stating that the premises are ready for disinfection, and mails it to the department. A disinfector is then sent who disinfects and removes the warning placard. The disinfector, after disinfecting the premises, fills out and mails postal card (Form 12) to school, Sunday-school and factories which were previously notified of the case, stating that restrictions placed on the family have been removed.

If a positive culture is found in a diphtheria contact, the quarantine is continued until a negative is obtained. One negative culture is required from contacts and two negative cultures made on two consecutive days are required from the patient.

Scarlet fever is quarantined in the same manner as diphtheria, except that no cultures are taken unless mixed infection is suspected. Quarantine is more prolonged in scarlet fever than in diphtheria. Four to six weeks, and in some cases longer, should be the quarantine period in scarlet fever. The instruction card (Form 13) and circular of information for scarlet fever are similar to that for diphtheria, only differing in some details to meet the requirements of this disease.

Measles cases are placarded and children in the house are kept from school and from visiting other children. No visitors are allowed in the house. The adults, if they have had measles, are allowed to go about their necessary work but are not allowed to go to church or other public gatherings. The period of quarantine should be three weeks or more. A circular of information on measles is given the family (Circular Form 4).

A warning card is posted for whooping-cough. The same rules of quarantine apply in cases of whooping-cough as in measles except the period of quarantine is eight weeks, or until the spasmodic stage has passed.

All cases of chicken-pox should be visited by a diagnostician unless the doctor reporting the case says that the subject has a successful vaccination. No warning card is posted for chicken-pox, but the patient is kept in for two weeks.

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Mumps is important only because it may get started and break up a school. Patients and those exposed should be excluded from school for three weeks. No warning card is posted.

When typhoid fever is reported to the department of health, a medical health officer visits the home from which the case is reported to learn, if possible, the source of the infection, and to instruct the attendants how to destroy typhoid contagion and prevent communicating the disease to others. He inquires into the water, milk and other food-supplies and learns if the patient has been away from home just preceding the attack, and other information required to fill out the report. He fills out report blank 14 and mails it to the department of health. A milkman's warning card (Placard Form 2), previously mentioned, is placed on the rear door and a circular of information on typhoid is given to the family and verbally explained (Circular Form 5). If screening against flies and proper treatment of discharges from patient are not practiced, the patient is ordered to a hospital. At the termination of the case, disinfection with chlorid of lime and formaldehyd is performed when conditions are such as to require it.

In the event of the milk-supply being suspected, a dairy inspector is sent to the farms in the country from which the milkman receives his supply, to look for possible sources of infection. If the source is located on any farm, shipment of milk from that place to the city is prohibited.

When a suspected case of contagious disease is reported, no warning card is posted until a diagnosis is made. The physician reporting has the family take all precautions and makes a second report as soon as the diagnosis is made.

The work in the schools done by the physician and nurse is conducted as follows:

At the beginning of the school term, the school doctor and nurse visit the school and make a rapid inspection to determine if any are seeking admission who show evidence of a contagious disease. This preliminary inspection is conducted in the following manner:

The doctor and nurse visit each schoolroom, stand with their backs to the window and have the pupils file past, exposing to view palms of hands and wrists. With the finger, the pupil pulls down the eyelid, exposing the conjunctiva, opens the mouth and puts out the tongue. Skin diseases, eye diseases and convalescent cases of scarlet fever can in this manner be detected. This preliminary examination is completed in a day or two and the school term is under way with the pupils found to have contagion about them excluded. They are excluded if on inquiry they are found to be coming from a house where a contagious disease exists. From that time on the school physician and nurse visit the school daily. The nurse makes routine daily inspections for evidence of contagious and parasitic diseases and refers all suspicious cases to the school physician for examination.

All pupils absent from school for three or more consecutive days and all suspicious cases found by principal, teachers and nurse are sent to a room to await examination by the school physician before they are allowed to go to their class-rooms.

If a case of diphtheria is found in school or if such case was in a class room and is found to have diphtheria the school physician takes cultures from the throats of all pupils in the class of which the sick pupil was a member. If a positive culture is found in any pupil, he is sent home and quarantined as a carrier of diphtheria germs, though there may be no evidence of sickness. A special quarantine placard is used (Placard Form 3) and a circular of information (Circular Form 3) is handed the family.

In Chicago, nine carriers of diphtheria were found in one class room, eleven in another, thirteen in a third, and the highest number found and quarantined was twenty-three in a class of twenty-seven.

In every instance in which an outbreak of diphtheria was found among the school pupils this practice of quarantining the carriers promptly and completely eliminated diphtheria from the school. There was very little opposition to this quarantine. We encountered the most opposition from physicians. With the department circular in their hands the parents of the child generally complied with the requirements of quarantine with little complaint. Complaints against the quarantine were usually the result of the information furnished by the physician called in by the parents. Physicians quite frequently protested against quarantining carriers. The opposition by physicians against this practice has continually grown less and now is quite infrequent.

REPORT OF COMMITTEE ON METHODS OF CONTROL OF SMALL-POX*

I. CONTROL OF SMALL-POX IN A CITY WITH A MILLION INHABITANTS

Heman Spalding, M.D.
Chief of the Bureau of Contagious Diseases, Chicago Department of Health
CHICAGO

The one agency, vaccination, is sufficient to absolutely prevent small-pox in cities large or small if this remedy is universally and intelligently applied. But there are always those in a community who oppose anything which was not created by themselves. I have never known an antivaccinationist who has had any experience with small-pox. One case in the family of an antivaccinationist has always cured him of his antivaccination views.

A small-pox hospital is a reflection on the intelligence of some of the citizens of a city. The burden of supporting such a hospital should fall on those who oppose vaccination. It is a needless expense and those who are careful to keep themselves immune from small-pox by vaccination should not be taxed to support hospitals for the care of a disease which is absolutely preventable by a universally known simple remedy.

The same methods for preventing small-pox in large cities are applicable to small cities, but large cities present difficulties not met with in small cities. The constant influx of cases from the surrounding country menaces the large city to a greater extent than the small city. The areas of congested population, the numerous centers of foreign-speaking population in large cities who mistrust our ways makes it more difficult to control disease among them than is the case where but few such people are found. In large cities there is more opportunity for concealing cases of small-pox. There is less respect for law and the rights of others in the large city. One of the greatest obstacles in a large city is the fact that the per capita tax for contagious diseases is lower than in smaller cities. A small town will spend one to five dollars per capita in a few months to suppress an epidemic of a contagious disease, while a large city like Chicago would never think of spending even fifty cents per capita to keep contagious diseases out of the city. By expending large sums of money, a small city can secure vaccination of nearly all and get small-pox under control in a few months, even after the disease has been introduced, but it takes a large sum of money to do it.

In a large city, if vaccination is neglected until small-pox is introduced at numerous points, the chances of preventing an epidemic becomes small. When an epidemic is well started in a large city full of susceptibles no effort that is likely to be put forth will eradicate the disease in less than two years. If everybody were vaccinated the disease would cease at once. This seems a simple matter, but in a city of two million, if we were to set one million the task of vaccinating the other million, the task would not be completed in a year. To vaccinate and keep vaccinated a large population requires persistent and aggressive work all the time.

The decisions of the courts that say vaccination can be enforced only in the presence of an epidemic, is not based on the true nature of epidemics of small-pox in relation to vaccination. The requirements are that a community must be made and kept immune if epidemics of small-pox are to be avoided. It is too late to prevent disaster if we wait until small-pox is present. The community must be kept immune from this disease and there is no way to bring about this result except by compulsory vaccination. To wait until small-pox is present before enforcing vaccination is as foolish as it would be to wait until a building is on fire before enforcing the building ordinance which requires fire-proofing. In the meantime, when small-pox comes every case must be hospitalized and wholesale vaccinations begun.

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

The following directions to medical health officers in a large city have proved successful:

When notified of a suspected case of small-pox, the medical health officer goes to the case forthwith. An hour's delay may result in many needless exposures.

The following suggestions as to conduct in the presence of small-pox are observed so far as the circumstances of the case will permit with safety, the health officer being required to supply any deficiency in instructions which the individual case may demand for public safety:

When entering a house in which there is a suspected case of contagious or infectious disease, do not remove your hat or overcoat; keep the overcoat buttoned.

Do not shake hands with any one in the house. Do not sit down or touch anything in the house, and especially avoid touching the patient or bed-clothing. To expose the patient for examination, call on the patient or some one present to remove the patient's clothing for you. When leaving the house, have some one open the door so as to avoid touching an infected doorknob.

Except to vaccinate the inmates of the house, it is not necessary to touch anything about the premises, excepting the floor, with the soles of your shoes.

If these precautions are observed there is no danger of carrying the disease to others.

When it is determined the case is one of small-pox, fill out the history blank provided for the purpose, telephone the information to the department and promptly mail the filled blank to the chief of the bureau of contagious diseases.

Telephone instructions as to the disposal of the case, whether an ambulance or a carriage is needed, the amount of disinfecting to be done and the number of vaccinators needed.

In filling out the blank, secure a list of all who have been exposed in any way to the contagion since the first day of the sickness; learn if letters or laundry have been sent out from the house; if so, where and to whom sent; give the vaccinal status of those exposed, so far as you can.

It is the duty of the medical health officer to vaccinate, or see that some other officer vaccinates, all who are known to be exposed to the infection. Do not leave or allow this duty to be done by the family physician. It is the duty of the health officer to secure the consent of the patient or family for the removal of the patient to the isolation hospital. Do not leave this duty to the ambulance driver.

Until the ambulance comes, the case must be made safe. If it is necessary to police the house to secure safety, do so. After securing the prompt vaccination of all exposed persons it is the health officer's duty to see the exposed every other day for fifteen or twenty days. If the first vaccination does not take, repeat until it does take.

If there be doubt as to the diagnosis, vaccinate the inmates of the house, make the case safe to others and see the patient later.

A medical health officer must be courteous and tactful in carrying out the department regulations in cases of small-pox. He should be complete master of the situation, able to dispose of complications and duties as they arise. He should secure compliance with the ordinance without force, if possible, but if necessary use police power.

After the patient is removed to the hospital, the premises are disinfected. All who have been exposed must be kept where they can be seen by a health officer every other day for twenty days. If the exposed keep in touch with the health officers as indicated above, they can go about their business. No quarantine is needed for those exposed until symptoms of the disease are noticed. After the twelfth day following exposure, they should remain in the house until it is certain they have escaped the disease.

When a case of small-pox is discovered it is our custom to vaccinate every one within two blocks of the infected house in each direction. If the case is found in a lodging house, the lodging-house population of the city must be vaccinated and kept under close watch. Nightly visits must be made to these houses to vaccinate new arrivals. Those who die of small-pox are buried by the department officials in any cemetery designated by the relatives.

II. CONTROL OF SMALL-POX IN RURAL DISTRICTS AND SMALL MUNICIPALITIES

H. M. BRACKEN, M.D.
Secretary and Executive Officer, Minnesota State Board of Health
ST. PAUL, MINN.

The control of small-pox in the rural districts and in the smaller municipalities is to be secured in the same way as in the larger municipalities, viz., through vaccination. Small-pox cannot be controlled without vaccination.

The public demands quarantine for this disease largely because it is a loathsome and disfiguring disease. We should not mislead the public by catering to their unjust demands. Public sentiment may be humored to a certain extent but those who are responsible for the control of this disease have no right to yield to the extent of misleading the people. The people should know that quarantine alone will never control this disease. Further, we have no right to throw a heavy expense on a municipality by quarantine of small-pox in an attempt to do that which we know cannot be accomplished. Isolation is necessary to a certain extent but to give the public a sense of satisfaction or confidence in attempting to control the disease by isolation alone is a mistake. There are always a sufficient number of unrecognized mild cases, or concealed cases to keep the disease going, if we were depending for its control on quarantine or isolation rather than vaccination.

It is a common opinion that the infection of small-pox is air-borne for a considerable distance. This is a mistake. Like most other infections, this infection may be carried by articles of clothing, etc., but if the infection is to be passed from individual to individual there must be quite close and somewhat prolonged exposure. It is also a common opinion that the disease is carried by a second or intermediate person to a third person. This is not true. Individuals living in a house with a small-pox patient but not ill with the disease themselves will not spread the infection to others unless they have been in such close and prolonged contact with the patient as to have had a certain amount of the infectious agent attached to their clothing. In fact, the spread of small-pox by a second to a third person may be treated as a negligible quantity in a well-vaccinated community. Public opinion is ready to demand great inconvenience for many individuals and great expense for the community, in order to prevent the spread of small-pox, when, as a matter of fact, the disease may be controlled by the personal expense of vaccination only, or even no expense, for vaccination should be free to all those who wish to take advantage of the public vaccinators.

It is absurd for those of us who are entrusted with the education of the people in matters pertaining to preventable diseases to advise or even condone the use of illogical or unscientific methods in their control. Quarantine is a relic of barbarism. It accomplishes nothing unless carried out in a most inhuman way and at great expense. One has but to recall the old shotgun methods used in attempts to prevent the spread of yellow fever before other means of controlling this disease were known, to realize the difference between quarantine and scientific control of disease. With our knowledge of vaccination, there is no more reason for trying to limit the spread of small-pox by quarantine than there is for continuing the shotgun method of controlling yellow fever now that we know the disease can be controlled by simpler methods.

I presume there are few, if any, present who do not believe in the preventive influence of vaccination against small-pox. Why then is vaccination not universal? Simply because ignorant or misinformed individuals have sufficient influence with many state legislators to prevent the passage of compulsory vaccination laws or to secure their repeal when they already exist.

The leaders in the antivaccination movement have much to say about sore arms as the result of vaccination. We must admit that there are some sore arms following vaccination, but these are the result of infection, not of vaccination, and this infection, instead of furnishing argument against compulsory vaccination should be one of the strongest arguments in favor of it. Why? Because the more perfect the vaccination the less the liability of infection. Infection is due to the following: (1) impure vaccine; (2) faulty technic on the part of the vaccinator; (3) imperfect care of the vaccinated arm or leg after vaccination. With proper compulsory vaccination laws, all of these possibilities would be reduced to a minimum.

We often vaccinate in emergency—that is, when there is a small-pox scare—or we vaccinate just before the opening of school in the fall, the very worst time of the year. A great part of our vaccination is done, therefore, under the most undesirable conditions. If we had compulsory vaccination laws, any state could determine very closely the amount of vaccine that its public vaccinators would need each year, for this would be governed by the number of births, and the production of vaccine would then be carried on under the most favorable conditions. When vaccine producers do not know how much of their product will be needed they may be short in their supply when the heavy demand is made on them in emergencies, and then be compelled to produce vaccine for rush orders or in hot weather. If we had compulsory vaccination, the children would be vaccinated at the most advantageous period of life, viz., the cradle age, instead of during the school age. In the countries having compulsory vaccination laws there is no active vaccination carried on during the two or three hottest months of the year. In our country, where we try to secure vaccination through the vaccination of school children, we do the greater part of the work in September, one of the most undesirable months of the year so far as the vaccine is concerned and one of the months which is most conducive to arm infection after vaccination because of the heat and dust. If we had compulsory vaccination laws, with well-trained vaccinators to take care of the poor, we would not run so great a risk as we do now of having sore arms.

Although the influence of demagogues and misguided individuals is often greater with legislators than is that of scientific leaders, the need of educating the people as to the control of small-pox by vaccination rather than by quarantine is imperative, and it seems to me the method adopted in Minnesota in 1908 is worthy of consideration. This consists in (1) placing a premium on vaccination by allowing the vaccinated privileges not granted to the unvaccinated; and (2) refusing to endorse the expenditure of considerable sums of money in an attempt to control the disease by rigid quarantine. It is well known that certain communities that have tried to control small-pox by quarantine have failed, and have been compelled to go back to the old system of vaccination as a means of protection. Vaccination is a small expense to the individual.

I wish to emphasize the fact which I have already stated, that quarantine is simply a relic of barbarism. There are only a few diseases that are now under quarantine regulations and most of these are diseases in which quarantine was chosen as the means of control before anything was known as to the cause of the disease. Fortunately, in most instances in which the cause of the disease has been discovered, scientific methods for its control have been adopted and rigid quarantine abandoned. Take yellow fever as an example. A few years ago an outbreak of yellow fever demoralized commerce and interfered with the carrying out of the general intercourse of the community, but when it was found that the infected mosquito was the only means of transmission the old system of quarantine was thrown down.

New diseases come up and we study them carefully. Take epidemic anterior poliomyelitis as an example. In the olden days undoubtedly the public would have demanded that health officials establish a rigid quarantine. At present the people ask the public health officials about the probable danger and are given advice. Instead of establishing a rigid quarantine, it is sufficient to point out the lines of probable infection and establish a system of isolation, similar to that used in Minnesota under the regulation that reads as follows:

> Every case of epidemic anterior poliomyelitis shall be reported to the local health officer at once. The patient shall be isolated for a period of two weeks from the onset of symptoms. All other children, teachers or others having to do with children residing in the affected household shall be kept under observation for a period of three weeks from the date of last exposure within the household; they shall not attend during this period day school, Sunday school or any public or private gathering whatever. Residence, boarding or lodging in a household during isolation therein of a patient suffering from anterior poliomyelitis shall constitute exposure. The discharges from the nose, throat and mouth of the patient must be received on cloths and burned at once. After death or termination of isolation all personal clothing and bedding of the patient, together with the contents of the room and the room itself, must be thoroughly disinfected under the personal supervision of the local health officer. In case of death a public funeral or viewing of the remains of the deceased is forbidden. Every doubtful case of anterior poliomyelitis shall be classed as of epidemic type and cared for accordingly until proved to be otherwise.

I think I have said enough to show that the control of small-pox is no different in the country districts and the smaller municipalties from what it is in the larger centers.

In January, 1908, the Minnesota State Board of Health put into effect the following regulations:

> The local health officer having knowledge of, or having reason to suspect the existence of small-pox, shall investigate and at once place on the house where small-pox exists a sign setting forth the facts. This sign is to serve only as a warning to those who may wish to avoid the house, and not as an indication of quarantine. When the attending physician considers a small-pox patient as having recovered he shall report the fact in writing to the local health officer, who shall thereupon remove the warning card from the house. The patient must not leave the house until after the removal of the warning card.
>
> The apartments occupied by a small-pox patient shall be deemed infected, and when vacated by death or removal of the patient shall, together with their contents, be thoroughly disinfected under the supervision of the local health officer.
>
> Every physician shall immediately report to the local health officer, in writing, the name of every small-pox patient under his care, the state of his or her disease, and his or her place of residence. A report must be made for each case as it occurs in a family or household.
>
> Every physician shall report, in writing, to the local health officer the death of any small-pox patient under his care within twelve hours thereafter.
>
> The local health officer of any city, village or township must report within twenty-four hours to the secretary of the Minnesota State Board of Health all cases of small-pox occurring within his jurisdiction, and the date of removal of the warning card.
>
> Following an exposure of small-pox, every individual who cannot show evidence of a recent successful vaccination or a recent attack of small-pox must be vaccinated (within three days of the first exposure) or placed under the same isolation restrictions as small-pox patients.
>
> If small-pox prevails in a community, or if the disease appears in a school, all unvaccinated teachers and pupils must be excluded from school for a period of three weeks unless vaccinated within three days of first exposure. Failing to comply with this requirement, the school must be closed for a period of three weeks.
>
> If small-pox appears in any class in any college in Minnesota, all unvaccinated teachers and students in the class must be excluded from recitations for a period of three weeks unless vaccinated within three days of the first exposure. Failing to comply with this requirement, the classes attended by such teachers or students must be discontinued for a period of three weeks.
>
> All persons having been ill with small-pox must have their clothing disinfected and take a disinfecting bath before being released from quarantine.

These have proved quite satisfactory. They call for the isolation of the patient without a quarantine on the premises. They place restrictions on the unvaccinated but grant privileges to the vaccinated; in other words, they penalize the unvaccinated and put a premium on vaccination. Through these regulations Minnesota, a state without compulsory vaccination laws—in fact, a state with antivaccination laws—has secured a fair degree of vaccination, for the people realize that they must protect themselves both from the disease and from the inconvenience of restraint in the event of exposure.

ABSTRACT OF DISCUSSION

ON REPORTS OF DRS. SPALDING AND BRACKEN

DR. E. STUVER, Fort Collins, Colo.: I am highly pleased that so distinguished an authority as Dr. Bracken takes the stand that he does on the question of quarantine. The world has been scourged with small-pox; between the years 1700 and 1800, one hundred millions of people died in Europe from small-pox; and Macaulay tells us that at one time scarcely a person could be found in London who was not marked or disfigured by that disease. Since Jenner discovered vaccination, no one who does not want small-pox need have it. What does quarantine do? It gives us a wall behind which the antivaccinationists can hide; they cry to the public, "Isolate cases of small-pox"; and they can shoot into the scientific world with the material that they collect from all sources and keep up a battle of that sort; whereas, if we turned our small-pox patients loose, we would soon see those people taking to the woods. They would get vaccinated. As shown by the epidemic in England, and especially when the thing came very close home, the antivaccinationists got vaccinated, and they didn't take small-pox.

Swallowing the virus does not work out in the presence of real danger. It will do when the small-pox is in some other county. The principal thing that we want to impress on our communities is the fact that vaccination does prevent small-pox. We had an epidemic in our small town last spring; our health officer made a report in April that at that time we had fifty-eight cases of small-pox: fifty-three patients had never been vaccinated at all, and the remaining five persons who contracted small-pox had not been vaccinated within fifteen years. No person in the community who had been properly or efficiently vaccinated took small-pox. People will come to the physician and try to argue the question of vaccination. I tell them: "I don't care whether you get vaccinated or not; it is a good deal more in my pocket if you don't get vaccinated. As far as myself and my own family, and people whom I have to look after, are concerned, I vaccinate them. You can use your own judgment. It is your great American privilege to be vaccinated or not; do as you please." They yield gracefully in nearly every case. If you argue the matter they will keep you tired for a week, and probably then not be vaccinated.

The question of sore arms, I believe, depends on the person one is dealing with. I have explained it something like this: Some are absolutely immune against the disease. Vaccination will not "take" on them under any circumstances. There is another class who are highly immune. They have mild sores; the manifestations are mild and they soon recover. There is the ordinary case, that runs an ordinary course; there are no severe symptoms and the person soon recovers. There is a fourth class, who have quite a strong susceptibility to the vaccine poison; and those persons get quite sore arms and become quite ill from vaccination. A large percentage of this latter class would die from small-pox. In the fifth class are persons who are exceedingly susceptible to the poison of small-pox, and when attacked they die. An explanation of that kind made to the public sometimes clears up the atmosphere and shows that the reason some people have very sore arms is because they are exceedingly susceptible to the small-pox virus, and if they took small-pox they would surely die from it.

Dr. J. N. Hurty, Indianapolis: I heartily agree with Dr. Bracken in every respect except one. He said that quarantine and isolation (I don't know the exact differentiation or distinction between the two) are barbarisms.

Dr. H. M. Bracken, St. Paul, Minn.: Quarantine only.

Dr. J. N. Hurty, Indianapolis: Quarantine only is a barbarism. Well, perhaps it is; but I would advocate very strict isolation of a certain class of diseases (with which you are all acquainted), if not quarantine; yet we permit their victims to run loose in this world uncontrolled in any way whatsoever. I refer to tuberculosis and the venereal diseases. We are inconsistent in the way in which we conduct our affairs, both public and private; and this is one of the most glaring inconsistencies that I know of—that we should permit persons infected with the most terrible leprous diseases to go about unchallenged in any particular whatsoever. They are more dangerous than small-pox victims, a thousand times more dangerous. Yet we are all aroused, ready to pay great sums of money for the quarantine and isolation of the small-pox person but not for the other. So I would advocate the retention of quarantine and isolation to some degree, because such methods are not barbarisms entirely. Then there is another point in regard to small-pox which Dr. Bracken did not mention. Shall we any longer class it as a dangerous disease? It is less dangerous in my state than measles. We have reported at this time about 300 cases of small-pox every month and not a single death. Inquiry was made into the reports for three months, and none of the cases was severe. Physicians everywhere were disputing whether it was small-pox or not. I think it was; but it was so mild that the element of danger did not enter into it.

Dr. H. M. Bracken, St. Paul, Minn.: A distinction should be made between quarantine and isolation. By quarantine we should mean rigid restraint of infected individuals and those associated with them. Isolation means only the separation of the patient with little or no restraint on the movements of other members of a family. I believe thoroughly in the isolation of many diseases, such as measles, epidemic anterior poliomyelitis, typhoid fever and small-pox; and I would be glad to see the day when certain other diseases now in the quarantinable group were put into the group of diseases for which isolation is recognized as sufficient. In Minnesota the death-rate from small-pox is less than 0.5 per cent. I do not remember the exact death-rate for measles and scarlet fever, but it is considerably higher than that for small-pox.

PUBLIC HEALTH EXHIBITS FOR PERMANENT INSTALLATION *

Frank B. Wynn, M.D.
Director of the Scientific Exhibit of the American Medical Association
INDIANAPOLIS

Certainly no one will deny the assertion that man's greatest fund of information concerning the world about him is gained through the sense of sight. The objects seen are but so many exhibits. Furthermore, knowledge thus gained is more readily acquired and better retained than through the spoken word. It seems strange, therefore, that the exhibit method of instruction should not be more generally employed in the education of the young. How little is done in our public schools to develop a critical faculty of observation! Children are trained along abstract lines. They grow to maturity with eyes, which should be their greatest aids, and yet see not.

The earliest employment of the exhibit principle of instruction in educational work came through the museum. Art was first to profit largely by the application of the exhibit method. In recent times the commercial and educational world, through expositions and fairs, have made extensive use of the idea. These, however, have been transient in character and wanting in continuity of educational effect.

Health authorities have abundantly demonstrated that exhibits constitute the most effective means thus far used in educating the public on health problems. As ordinarily employed they are cumbersome, expensive in their initial cost and in their maintenance; they are shown only in the larger cities and towns, presented for a day or two, and not again for a long period. I would not be understood for a moment as decrying the usual methods now employed; they are most valuable and should be continued. My appeal is to supplement these efforts by permanently installed health exhibits, which will teach the lessons of hygiene and sanitary science day by day. The evangelical stage of health propaganda has been passed; let such agitation be followed by preaching and practicing a health religion in the daily life. Systematic and continuous instruction should constitute the second stage in the evolution of health methods; best accomplished through colleges, the high school and the public schools; and for the work-a-day citizen, permanently installed exhibits.

It is not the intention at this time to consider school methods of instruction on health matters, a phase of elementary education greatly neglected. It is only the exhibit aspect of the question that is now offered for consideration. The up-to-date teacher sees to decoration of the schoolroom walls with pictures of persons or things relating to the subjects taught. Frequently one may note the pictures of Shakespeare, Bryant or Emerson in illumination of literature; that of Washington, Jefferson and Lincoln in exemplification of war and statesmanship; but whoever saw the pictures of Jenner, Pasteur or Koch as great heroes and benefactors of mankind?

Until the curricula of our public schools include competent instructors on health matters, is there not something which health authorities may inaugurate which will leave a permanent impression on the child?

A compact sanitary exhibit, such as devised through the Scientific Exhibit of the Association, seems to me a step in the right direction. The exhibit shown at Los Angeles and previously described[1] contains thirty metallic leaves, easily removable, on which are mounted sixty pages of pictures, charts and

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Wynn, Frank B.: Public Health Exhibits Under the Supervision of the American Medical Association, The Journal A. M. A., Jan. 28, 1911, p. 294.

data. In this particular exhibit the subject of tuberculosis only is treated. Let such exhibits be placed in school buildings. Groups of these leaves might be removed at pleasure by health authorities and others substituted on a health topic of interest in the community. At one time a campaign might be waged on food adulteration; at another, on the evils of self-medication, "patent medicines," etc.; or the local situation might call for agitation on the subject of typhoid prevention. There are endless ways in which a public health bulletin of this character could be used by efficient health officers for systematic instruction on health subjects.

Other places in which the same type of exhibits might be installed permanently are notably, court-houses, city halls, railway stations and other public places where people congregate and find the opportunity to look and read. They would be especially adapted to villages and towns where large migratory health exhibits do not go.

The American Medical Association could engage at this time in no work of greater practical value to the public health than in the standardization of data and material for small exhibits of this character, making the product so cheap that it would be available for remote rural as well as urban districts.

ABSTRACT OF DISCUSSION

Dr. A. J. Reed, Battle Creek, Mich.: I was very much interested in this ingenious device that Dr. Wynn has presented, because it seems to me that it is really very practical. It is true that people waiting in railroad stations have time to kill; and, unfortunately, their idleness and ignorance endanger the health and lives of human beings. They are killing their neighbors for want of knowledge. The laity are wonderfully ignorant about the simplest principles of health. The suggestion of following up timely health subjects, such as typhoid, epidemics of small-pox and general health instruction in this manner, I believe will be very helpful and I hope that it will be remembered by those in attendance and put into practice. I believe that there is a moral obligation resting on the profession to educate the people on the prevention of disease and the preservation of health. We should not leave this opportunity to be used by quacks and fakers. I don't know how some of us can do any better missionary work than by investing a few cents in similar attractive, modern devices for our own towns and counties and installing these silent messengers which are constantly at work, enlightening the people. The inroads which preventable diseases are making in spite of our best efforts, demand that we do more in the future than we have in the past for the physical salvation of our communities.

Dr. E. Stuver, Ft. Collins, Colo.: I would like to inquire of Dr. Wynn where those leaves can be procured and at what cost.

Dr. S. A. Knopf, New York: I think this is a most excellent and admirable scheme. It is particularly good to have a leaflet containing the antispitting ordinances; but in my experience it is utterly useless to say: "Don't spit." People will spit. Now, I believe it would be a good idea if, instead of our negative command, we would make a positive one, and say: "Spit here!" and with it provide a proper receptacle. I don't mean to say that all people spit; but some have colds and some use tobacco, etc. It is just as injurious to swallow the expectoration as to put it where it can infect others. There should be no railway station nor railway car without a proper and sensibly constructed spittoon. Those now in use in most Pullman cars are only fancy articles. They are so planned that the sputum in them always dries; and I pity the poor porter who has to clean them. For railway stations, public places and health resorts I believe in the automatic self-cleansing spittoons. We ought to have them everywhere in sufficient numbers, since we now know that tuberculous sputum is the main cause of infection from man to man. Spitting on the sidewalk should be prohibited; but on the other hand, I don't believe we should say don't spit at all. We should say don't spit on the sidewalk, don't spit where people walk. We might then induce people on the street, where there are no proper receptacles, to spit in the gutter. This would be an improvement on existing conditions.

Dr. Frank B. Wynn, Indianapolis: This exhibit and three other models have been developed as part of the Scientific Exhibit. Prizes were offered two years ago with the view of developing compact and durable exhibits. These have been the outcome and have the endorsement of the Council on Public Health. There are three models. This one relating to tuberculosis sold at $15.00. There is a size a little larger that costs $20.00; and there is a wall kind that folds and lets down, containing the same data, and also large placards, which sells also for $15.00. Considerable reduction in prices over those given may be secured if the exhibits are purchased in quantities. These can be bought through the Council on Health and Public Instruction of the American Medical Association, at the Chicago office, or of Clark & Roberts of Indianapolis, who have been the manufacturers thus far.

THE PSYCHOLOGIC ASPECT OF REFRACTION *

S. L. LEDBETTER, M.D.

BIRMINGHAM, ALA.

While refraction is a science based on mathematical principles and theoretically very exact, yet there are other questions involved besides that of measuring the radius of curvature, finding the far and near points, range of accommodation, etc.

What I shall have to say in this short paper will not be new to many, but it is a phase of refraction about which very little has been said or written. Hence my excuse for presenting this paper.

Has psychology any practical bearing on the subject of refraction? In many cases perhaps very little, while in other cases quite a good deal. If all brains were of the same quality, all minds trained to think alike, all nervous systems equally well balanced, every individual reared in a pure atmosphere with proper and healthful environments, refraction would in a measure be reduced to the simple question of accurate observation and correct measurements. It would be largely mechanical. But as such conditions do not and cannot exist, we are bound to recognize the right of psychology to a place in refraction. We must in every case consider the individual with all his idiosyncrasies and eccentricities. Refraction to the beginner is a fascinating subject. It appeals to him because of its exactness. It presents problems which he can work out for himself, and he can prove the correctness of his conclusions. He is therefore liable to underestimate the gravity of the subject, and to overlook one of the most vital features of it; that is, the individuality of the patient, as well as that of the examiner. I shall not attempt to go into the philosophy of mental suggestion or to discuss the various theories of psychic phenomena, because it is not necessary or expedient to do so, and the field is too broad.

We are compelled to admit that there is a psychologic phase to every situation in which two minds are brought in close relationship; where the personality of the one appeals to that of the other, and where a motive exists for the obtaining of a sympathetic relationship between the two. To have a strong personality, or to be possessed of what is usually termed personal magnetism, is a very necessary element of success in any calling in life, and it is worth as much to the refractionist as to any other. In fact, the refractionist who does not possess a reasonable amount of the faculty is handicapped.

---

* Read in the Section on Ophthalmology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

The fitting of glasses to presbyopes, in a large percentage of cases, does not call for any great skill or an extensive knowledge of scientific refraction, but does require a reasonable amount of common sense and a good knowledge of human nature. These patients are not hard to please, as a rule, and are satisfied with vision which enables them to read ordinary print without much effort. This assertion applies, of course, to the rank and file of those who have accepted the portion of senility, who have worn off the wire edge of enjoyment and have resigned themselves to the simple life. I have seen patients with decided astigmatism plodding along contentedly with a very indifferent pair of spherical lenses, in frames set all askew. A person of this class of humanity is easily imposed on by the unscrupulous spectacle-vender, and can usually fit himself if you will furnish him with a few pairs of glasses from which to select. There are others, however, who have very decided ideas of the dangers which may come from the wearing of glasses incorrectly fitted and who would be very unhappy if they had been fitted by one in whom they had not the utmost confidence. And still, they may not be unreasonable in their requirements and need only to be assured that they have had a proper refraction and that their glasses are correct.

There are others, however, who are skeptical and disposed to find fault. They are never quite sure of anything; are afraid to admit that they see any better with one lens than another, lest they make a mistake and mislead the refractionist. They will hesitate as to the relative clearness of two lenses, trying first one, then another; then they will go back to the first again, and so seesaw back and forth until the refractionist has exhausted his stock of patience and nervous energy, and the patient is in such a state of uncertainty that he cannot render any intelligent assistance. Perhaps the most sensible thing to do in this case would be the postponement of the work to another day. This gives the refractionist time to take the measure of this patient and plan his campaign, when, perhaps, by bringing to bear a large amount of his own personality the patient may be made to accept a correction. A patient of this class is likely to give the physician more or less trouble later. for having a doubting disposition he will do some testing on his own account and return from time to time with his grievances. Whether the grievance be real or otherwise does not much matter, for he thinks it is a real one and the case must be given some attention. If the refractionist feels sure that he has given a proper correction, then it becomes a question of dealing with the mental attitude of the patient. Confidence must be established and ghosts of imaginary evil and preconceived ideas of dire calamity must be dissipated. With this class of patients there is a fertile field for the exercise of a strong personality and psychologic influence.

Much more might be said along this line, but I wish to discuss briefly another phase of humanity, one of the most troublesome types with which we have to deal; i. e., the man (or woman) who thinks that glasses would in some way or other be an advantage to him. He has diagnosed his own case by introspection or reading quack advertisements, or else he thinks that glasses will lend a certain appearance of respectability or intellectuality, and insists on having them. The individual of this particular type is usually ignorant and could get on just as well without glasses as with them, even if he should happen to have a small amount of ametropia, but he wants them and will very frequently deceive the examiner—unintentionally, perhaps. His anxiety to obtain the glasses will lead him to say that he sees better when he really does not, and nearly any lens placed before him is good. His replies cannot be depended on at all as to how well he sees. The only sure test is to make him call the letters, if he knows them. Sometimes, however, he will say that a certain lens is an improvement, not from any intent to deceive, but because he is led on by mental suggestion to say that he sees better or worse. He is impressed with the idea that he is expected to see better, and answers the question accordingly, but when called on to read the letters he stumbles as badly or even worse than before.

While I do not approve of suggestive therapeutics or hypnotism as practiced by the ill-advised or the charlatan, I do recognize that much can be done with individuals of this type by mental suggestion. They have very plastic, impressionable minds. They are credulous and more or less superstitious and easily imposed on, and are the legitimate prey of the unscrupulous. Still this same unexplainable something which we call personality, this power to impress and inspire confidence, is a very potent one, and the refractionist who is lacking in it will experience great difficulty in leading the patients along lines of least resistance to correct conclusions. It is also necessary to be a good judge of human nature, to be able to interpret mental attitudes of a patient, to recognize elements of hysteria and detect symptoms of remote reflexes and neuroses, to be able to say to your patient that, with the restoration to a normal condition mentally and physically, all eye symptoms will pass away. More than this, it is necessary to carry conviction to the mind of the patient and furnish a substitute for all his preconceived ideas. Sometimes it seems advisable to compromise with him and give glasses when one is convinced that there is no real need for them. Some of these patients come to recognize in time that they get on just as well without their glasses, and lay them aside, while others continue to wear even plain glasses with a great deal of confidence and will stoutly maintain that their eyes soon grow tired and give trouble when the glasses have been left off.

So the glasses have served a good purpose and the end has justified the means in a measure. With the conscientious physician the bringing to bear of all of these faculties and forces, if the interest of his patient be subserved, is a perfectly justifiable procedure; it is honorable and legitimate. But with a refractionist who is looking only to the monetary side of the question, or with the quack spectacle-vender, whose mission is to sell glasses regardless of the requirements of the case, the exercise of this faculty becomes a means of perpetrating fraud, and cannot be too severely condemned.

ABSTRACT OF DISCUSSION

Dr. G. C. Savage, Nashville: Psychology has a great deal to do with refraction. How to make the psychologic impression is the question we should ask ourselves and we want to be able to answer it. In the first place we will need no psychology if the patient has only one eye and there is no inflammatory trouble in that eye. To make a proper psychologic impression on the patient a thorough examination should be made, not only as to the refractive error, but also as to the condition of the ocular muscles. A patient with hyperphoria even of half a degree is going to complain if this is not corrected. If he is told that he has it and that you are going to correct it the effect follows, not only from the psychologic impression, but also from the prismatic power of the lens. Many times I have gone over the refraction of patients who had been to my confrères and found absolutely no necessity for a change of lenses except as to prismatic correction of a hyperphoria of low degree. If in giving a prism it is placed before the hyperphoric eye there is always relief. If there is exophoria in the near and your patient has a hyperopia and you attempt to give full correction without paying attention to the exophoria in the near, then you are going to get into trouble, psychologic effort or not. If there is esophoria in the near with hyperopia and you fail to give full correction then you are going to have trouble and no suggestive effort will avail. If an astigmatic patient needs plus cylinders with axes diverging, these will make a rectangle look broader at the bottom and he will feel that he is walking up hill for a few days. But the patient can be told this beforehand and the mental impress does good. He or she can be assured that this annoyance will vanish shortly and no complaints will follow. But plus cylinders having their axes converge above will make the patient walk down hill (the rectangle will be broader at the top) and that condition will last four to ten times longer than the other trouble. If you tell the patient this beforehand you make a psychologic impression and he patiently becomes accustomed to his glasses. Another fact which should be told the patient that makes a good psychologic impression is that a straight line should always pass through the four joints of the spectacle frame, and that his lenses must be level before his eyes.

Dr. C. D. Wescott, Chicago: Just one word with regard to the treatment of our presbyopic patients. It seems to me that the decade in which we should be most careful is between 45 and 55. It is certainly the time of life when I use cycloplegia with the greatest care and in which I make the greatest effort to correct low grades of astigmatism. I have one patient, a physician 66 years of age, who will not accept a cylinder unless the eye is under the influence of a cycloplegic. Under homatropin and cocain he accepts half a diopter cylinder and is more comfortable both in reading and for distance. It has been my practice for years to use atropin, in the absence of any contra-indication, in all patients under 40, who are not comfortable in glasses prescribed under homatropin, and in patients over that age I use homatropin and cocain, 2 per cent. each, a half dozen drops in each eye at intervals of five minutes, waiting an hour and fifteen minutes before making the tests. I use it up to 70. Frequently I do not use the full dosage, but I use it in practically all patients in whom there is no contra-indication.

Mark D. Stevenson, Akron, O.: I think one of the most important things, aside from the refraction, is to outline to the patient the difficulties in becoming accustomed to the lenses and their proper use. Years ago I had a large envelope printed stating the reasons why patients would not at first be satisfied with their lenses, although proper. An assistant also very thoroughly explains, with suggestions from me, why at first they will have difficulty. I feel that this is of very great importance from the psychologic standpoint. In addition to this a thorough explanation is made of how to wear the lenses. If this is not explained to patients their control will be more difficult. I think if we can foresee probable difficulties and explain that these often occur in a patient correctly fitted, and must be expected, that it is of the very greatest importance from a psychologic standpoint. I think one of the chief reasons for using atropin instead of homatropin under 45 or 50 years of age is that it assists the patient in quickly becoming accustomed to his lenses and is not merely used to find the static refraction. It also gives the patient's eyes a rest.

Dr. Edgar S. Thomson, New York: I think it is very important indeed to prepare the patients for just what they are going to experience. In the first place the action of the eyes is a matter of the coordination of a number of different muscles, and delicate acts of coordination must always be subconscious in order to be perfectly easy. There is a very decided analogy, to my mind, in becoming accustomed to new conditions in coordination of the eyes, to learning a new passage on a musical instrument, say the piano. It must be carefully drilled into the memory first of all and then it must be played without thinking of the individual action of the fingers; in other words, the coordination must be in the subconscious mind. Now, if patients get a lot of unexpected symptoms that disturb them when they first put on the glasses they immediately begin to try to pull around them, and try to adjust themselves to them, which is just what they should not do. Therefore it is important in any change of refractive conditions to have them prepared so that they will drift with the tide instead of fighting it.

Dr. W. E. Lambert, New York: All this is a tempest in a teapot. Most of the people we have to deal with cannot understand these details. We presume of course that any man who attempts to fit glasses knows his business and makes a thorough examination, but the subjective tests may show up somewhat differently, and he has to use his common sense in dealing with the different patients. This applies to fitting glasses, giving medicine or anything else, and to my mind that is what Dr. Ledbetter tried to bring out in assuming scientific knowledge. He says it is a fascinating subject. I have not found it so. Refraction is a tiresome and tedious thing. It reminds me that we must at times be all things to all men. It is quite legitimate to dissemble if we do it for the benefit of the patient. A woman had a pain in the back of her head. I said, "That is a matter for your family physician and I should like to consult with him about your case." She said, "I have none; I am a mental scientist." I said, "By an extraordinary coincidence so am I. I thoroughly believe in bread pills when they are indicated, but I also believe in calomel when it is indicated. Now your condition is not for mental science or for bread pills." We must deal with these people according to their mental caliber.

INTRA-UTERINE OPHTHALMIA NEONATORUM

W. A. NEWMAN DORLAND, A.M., M.D.
CHICAGO

The development of gonorrheal ophthalmia in a fetus *in utero* is so extremely rare that it becomes almost obligatory to place such a case on record. The textbooks in almost every instance fail to mention the condition, even as a possibility. A communication, recently received from Dr. F. Park Lewis, Chairman of the American Medical Association's Committee on Prevention of Blindness, states that, while it is a very unusual occurrence, intra-uterine ophthalmia has been recognized for some time. The condition was first noted by Quellmalz in 1750. Demours,[1] Guthrie,[2] Hilsenburg and Hasse[3] were among the earliest to report cases. They were followed by others, and more recently, by Queirel,[4] in 1902, and finally by Sydney Stephenson[5] in 1907, who tabulated 90 cases collected from literature and encountered in his own experience. In all literature to date about 100 cases have been recorded. Some interesting facts are to be noted, as follows: Not only the gonococcus, but the pneumococcus, colon bacillus and other germs may be the causative agent; the gonococcus, however, is by far the most common cause. In only a little over one-third of the cases was premature rupture of the membranes noted. In the other two-thirds (63 per cent.) the membranes ruptured at some time within twenty-four hours of the birth of the child, too late to permit of antenatal development taking place. A few cases of fully developed ophthalmia have been recorded of children born in a caul. Other cases are reported in which the ophthalmia had apparently run its course *in utero,* leaving damaged corneas or atrophic eye-balls. Beyond controversy the increased temperature of the conjunctival

5. Stephenson, S.: Ophthalmia Neonatorum.

sac *in utero* enhances the virulence of the causative microorganism, and this, together with a lack of resisting power on the part of the infant, results in the extremely acute course of these cases. Placental transmission has been suggested as a method of infection *in utero*, but Stephenson believes that most of the cases are to be explained by the theory of a local intra-uterine infection—penetration of the intact membranes by the germs. Infection in the case I am about to report undoubtedly took place because of a premature rupture of the membranes.

Mrs. X, aged 24, the wife of a medical student, was admitted to Jefferson Park Hospital on the morning of Jan. 13, 1911, well advanced in the first stage of labor. The bag of waters had ruptured spontaneously seven days before, while the patient was engaged in her usual household affairs, but there had been no labor pains until the midnight before her admission to the hospital. Labor was easy and uneventful, without complication, other than a trivial fourchet tear. When the nurse attempted to instil the silver solution in the baby's eyes they were found to be the seat of an advanced gonorrheal ophthalmia. A greenish pus was exuding in large quantities from each eye, and the conjunctivæ were deeply injected, presenting a vivid red appearance. So virulent was the case, that, in order to prevent the remotest possibility of infection of the other babies in the hospital, the child and mother were immediately removed to the Illinois Charitable Eye and Ear Infirmary, where prompt and energetic treatment of the eyes was instituted. Notwithstanding the excellent care the baby received at this institution, one eye became perforated the following day and was destroyed, and the other showed almost complete corneal opacity from ulceration. The mother passed through a normal apyretic convalescence.

The points of interest in this case are the early rupture of the bag of waters, one week prior to the onset of the labor pains; the apyretic course of the mother's case in the presence of a virulent vaginal infection; and the infection of the child's eyes during the week subsequent to the rupture of the membrane while the fetus was still *in utero*. It is interesting to conjecture how the gonococci gained entrance to the uterine cavity, since the mother denied all vaginal douching prior to the delivery of the child. The freedom of the mother from gonorrheal puerperal fever was due to the fact that the infection had occurred within the amniotic sac and had been thereby limited to that cavity without penetration to the decidual tissue.

THROMBOSIS OF THE MESENTERY CAUSING GANGRENE OF THE ILEUM

R. W. WAKEFIELD, M.D.
BAR HARBOR, ME.

I report the following case for two reasons; first, because thrombosis of the mesentery is rarely seen and never diagnosed except at operation or post mortem; and second, because this patient made an uninterrupted recovery from this surgical affection which is usually attended by a very high mortality.

History.—W. T. H., a white man, married, aged 60, was a merchant. Family and personal history were negative. For the past twenty-five years he had suffered occasionally from so-called "bilious attacks," in which he would be taken suddenly with nausea, vomiting and epigastric pain after some indiscretion in diet. Attacks would last from a few hours to two or three days, after which time the patient would feel perfectly well again; was never jaundiced. Two and one-half years ago he suffered from bronchopneumonia but made a good recovery. Since convalescing from pneumonia he has enjoyed good health until present illness. Two weeks before illness came on he took a long horseback ride but felt no inconvenience from the exertion, except general muscular stiffness which soon disappeared. On the morning of July 8, 1911, the patient was in his usual health until 10 a. m. when, while riding in his carriage, he was suddenly taken with severe abdominal cramps, nausea, vertigo and faintness. In a few moments vomiting began.

Examination.—His family physician, Dr. George Neal, found patient prostrated, vomiting frequently, mostly mucus and water; complained of severe pain in epigastrium, chilliness and frequent desire to go to stool. Pain was paroxysmal but not colicky; patient complained that pain would rise in throat, choke him and make him feel faint. Countenance was cyanotic, pulse 90, feeble and intermittent. Palpation over abdomen showed no particular point of tenderness, but whole abdomen was distended and greatest pain seemed to be in epigastrium.

Course.—A high enema was given with small result. Patient's bowels had moved normally at 7 a. m. Distress was so great that ¼ grain of morphin was given. At 5 p. m., pain had ceased and patient felt comfortable, with pulse 90, regular. At 9 p. m., distress and vomiting returned and continued at intervals during the night.

July 9, 10 a. m., pulse 110; abdomen was distended and tympanitic; there was an area of dulness at McBurney's point; diffuse tenderness. At 12 a. m., vomitus was of coffee-ground character; a high enema of salt solution came away almost clear. At 2 p. m., stercoraceous vomiting began. Pulse 120, feeble; temperature 100. In spite of the administration of calomel, salines and high enemas, constipation was complete.

I saw the patient at 6 p. m. Face pallid and expression anxious; breath foul. Mental condition normal. Found a few coarse râles at the base of both lungs; lungs otherwise normal; pulse, 120; heart sounds weak; abdomen moderately distended, right side more than the left; recti muscles very rigid. A distinct tumor about 2½ inches in diameter could be palpated at McBurney's point. There was marked tympany over abdomen everywhere, except at site of tumor. Note over tumor was dull but not flat. Temperature 100 2/5 F. A diagnosis of acute intestinal obstruction was made and the patient was hurried to the Bar Harbor Hospital, 18 miles distant.

Operation.—At 11 p. m. right rectus incision was made over most prominent part of tumor. Peritoneum was very dark in color; when opened, a large quantity of serous fluid escaped. Ileum immediately presented itself in the wound, black in color; gangrenous for about 30 inches. Mesentery was gangrenous for about half its depth, and all the vessels were thrombosed. No other lesion was found. The gangrenous bowel and its mesentery were quickly resected and anastomosis made with Murphy button. The abdomen was closed with through-and-through silkworm gut sutures without drainage.

Recovery.—Patient suffered but slight shock from the operation and reacted well under treatment. Murphy button was recovered on tenth day. The patient made an uninterrupted recovery and feels perfectly well one month after operation.

I want to acknowledge my indebtedness to Dr. Neal for the privilege of reporting this case.

16 High Street.

The Sacred Disease.—In the time of Hippocrates the Greeks called epilepsy the "divine ill" or the "sacred disease." Cullen says that it was so called because the ignorant thought it the result of divine punishment. Some of the old books say that the Sibyls rendered their answers in the midst of epileptiform convulsions. That the entire nation was not so densely ignorant nor superstitious regarding its origin, however, is proved by this remark by Hippocrates: "It appears to me to be in nowise more divine or more sacred than other diseases. Men regard its nature and cause as divine from ignorance and wonder because it is not like other diseases."—E. L. Hunt in *Medical Record.*

AN AVOIDABLE ACCIDENT DURING LUMBAR PUNCTURE

W. F. LORENZ, M.D.
MENDOTA, WIS.

While I had long entertained the possibility of breaking a needle during lumbar puncture, yet the accident happened only after a large number of punctures had been performed.

The patient was in the lateral position on the left side and fully flexed. He was held in this position by an attendant with one arm beneath the patient's knees and the other about his neck. Ethyl chlorid was used as a local anesthetic. The puncture was made in the fourth lumbar interspace just to the right of the median line and close to the upper border of the fifth spinous process. The patient apparently did not heed the entrance of the needle until its point was in the neighborhood of the canal, when he suddenly extended his back and the needle snapped, leaving 4 cm. well below the cutaneous surface. The patient was immediately anesthetized and a search made for the needle, without success. Three days later an *x*-ray picture was made and showed the needle lodged close to the upper border of the fifth lumbar spine. The patient was again anesthetized and the needle was easily removed.

This accident can be avoided if means are taken to prevent a sudden extension on the part of the patient. I have subsequently employed a simple contrivance, consisting of a light padded stick placed beneath the patient's knees and attached by means of light straps to canvas bands coming over the shoulder and beneath the arm-pit. The bent knees can be drawn as close as desired and consequently extreme flexion of the spine is obtained. This is desirable for successful puncture and the appliance makes sudden extension on the part of the patient impossible, thus safeguarding against accidents similar to the one reported.

Another fact brought forcibly to mind was the difficulty in finding the fragment of needle, although its approximate position was known. This emphasizes the help that can be derived from a skiagraph, as this showed the needle plainly in its relation to the spine and likewise gave its depth below the cutaneous surface.

It may be added that the patient experienced no ill effects from the presence of this fragment of needle. Shortly after the accident until the time of its removal, he was up and about.

OPSONOTHERAPY IN A CASE OF PUERPERAL SEPSIS

W. C. WOLVERTON, M.D.
LINTON, N. D.

History.—Feb. 3, 1911, I was called to a neighboring village to see Mrs. J. G., a German-Russian woman, quartipara, aged 24 years. This was on the twelfth day of the puerperium. The labor had been attended by a Russian midwife, who, in order (as she thought) to facilitate labor, had stuffed the vagina of the patient full of lard, which latter had stood in an open can in the kitchen for quite a while before being put to this rather remarkable use. It might be well to remark here that the midwife had not been guilty of washing her hands, even with water, before making any of her numerous examinations.

Examination.—When I first saw the patient, February 3, her temperature was 103, pulse 120; she had had chills for several days (it is impossible to get exact data from these people); severe headache; pains in back and limbs; anorexia; nausea and vomiting; in fact, all the symptoms of a profound sepsis. Also, there was a noticeable mitral murmur; no history of previous acute rheumatic arthritis, scarlet fever, etc. could be elicited. The abdomen was bloated, and very tender over the large, flabby uterus. From the vagina issued a stream of foul-smelling pus. Examination did not reveal any retained secundines.

Treatment and Course.—As it was impossible at once to determine the exact nature of the infecting microorganisms, a culture-tube was inoculated with some of the pus, and a "shotgun" vaccine was administered. This vaccine contained 40 million *B. coli*, 30 million *Streptococcus pyogenes*, and *Staphylococcus pyogenes aureus* and *albus*, 100 million of each; this was injected into the subcutaneous tissues of the thigh, so as to have the locally-formed opsonins travel "upstream" toward the focus of bacterial activity, as recommended by Wright. Physiologic saline enemata and douches of compound solution of cresol were ordered to be given every three hours.

February 5, found the subjective symptoms markedly improved; there had been no further chills, and the temperature was lower, pulse less rapid, and headache, nausea, etc., relieved.

Meanwhile, the bacteriologic examination showed the presence of *Streptococcus pyogenes* and *Staphylococcus pyogenes aureus* and *albus*, with the streptococci predominating. No *B. coli* were found.

February 7, I was again summoned, and was told that the patient had had a severe chill. The temperature and pulse-rate had again risen. A vaccine containing *Streptococcus pyogenes*, 60 million, and *Staphylococcus pyogenes aureus* and *albus*, āā 200 million, was injected, and the douches and saline enemata continued as before.

February 12, the patient was again seen, and was found to be so much improved that no further visits were made. On the occasion of this last visit, a dose of vaccine identical with that of February 7 was administered. From this time the patient made an uneventful recovery, and is now in perfect health. The only remedies used internally in this case were calcium sulphid, calomel and soda, and elixir ferri, quininæ et strychninæ phosphatum. During the period of nausea and vomiting, liquid peptonoids were administered per rectum.

This case looked so hopeless at the first visit that I made a prognosis of probable fatal outcome. Also, there was no nurse to care for the patient, and the douches and enemata had to be entrusted to the husband, a Russian not overburdened with intellect. Consequently, the case seemed worthy of note.

The vaccines used were of the "stock" variety. Every time a dose was administered, there was an emphatic response within twenty-four hours.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

LUTEIN TABLETS, H. W. & CO.—Each tablet is said to represent 1.3 Gm. (20 grains) of fully developed corpora lutea.

Actions and Uses.—See Corpus Luteum.

Dosage.—One tablet, three times a day.

Manufactured by Hynson, Westcott & Co., Baltimore. Not patented or trademarked.

QUININE TANNATE—Quininæ Tannas.—Quinine tannate is the tannate of the alkaloid, quinine, containing from 20 to 35 per cent. of quinine.

Quinine tannate may be prepared as follows:

> Ten Gm. of quinine sulphate are dissolved in a mixture of 15 Cc. of diluted sulphuric acid and 150 Cc. of water. Twelve Gm. tannic acid are dissolved in 75 Cc. water and the filtered solution poured slowly and with constant stirring into the solution of quinine sulphate. Three Gm. tannic acid are then dissolved in 50 Cc. water and 3 Gm. sodium bicarbonate dissolved in 50 Cc. water. These solutions are filtered, the filtrates mixed, and the mixture poured slowly and with constant stirring into the quinine-tannin mixture prepared as above described. The precip-

itated quinine tannate is allowed to stand for 24 hours. It is then poured onto a muslin filter, washed with 100 Cc. water and expressed with moderate pressure. The expressed mass is then transferred to a porcelain dish, 50 Cc. water added and the mixture heated on the water bath until the quinine tannate melts to a resin-like mass. The supernatant liquid is poured off, the mass cooled, dried in the air and pulverized.

Quinine tannate is an amorphous, pale lemon-yellow to yellowish-white, odorless powder without taste, or at most slightly bitter, and with scarcely any astringency. It is slightly soluble in water, ether and chloroform, but somewhat more soluble in alcohol. Its aqueous and alcoholic solutions are colored bluish-black by ferric chloride test solution. Quinine tannate melts on heating in a glass tube to a purplish, tar-like material.

If 1 Gm. of quinine tannate be shaken with a mixture of 50 Cc. of water and 1 Cc. nitric acid and the mixture filtered, a portion of the filtrate should not become more than slightly opalescent after the addition of 1 Cc. of silver nitrate test solution; nor should there be any darkening after the addition of 1 Cc. of hydrogen sulphide test solution; nor should a portion be rendered turbid immediately by barium chloride test solution.

If from 0.5 Gm. to 1 Gm. of quinine tannate be mixed with 25 Cc. water and an excess of ammonia water, the mixture extracted with 3 successive portions of 20 Cc. each of chloroform, the total solvent washed with water and evaporated, the weight of residue obtained after drying at 100° C. should correspond to from 29 to 35 per cent. of anhydrous quinine. If this residue be dissolved in 30 Cc. of water by the aid of a few drops of diluted hydrochloric acid and 1 Cc. of the solution be mixed with 20 Cc. of water and 2 or 3 drops of bromine test solution, the mixture should assume a green coloration on the addition of ammonia water.

If 0.2 Gm. quinine tannate be ignited no weighable residue should be obtained.

If from 0.5 Gm. to 1 Gm. quinine tannate be dried at 100° C. to constant weight the loss should not correspond to more than 10 per cent. of the weight of substance taken.

If 2 Gm. of quinine tannate be shaken with 3 successive portions of 25 Cc. each anhydrous ether, the solvent poured through a filter, the filter washed with 10 Cc. of the solvent, the several filtrates united, evaporated and the residue dried to constant weight at 100° C. the weight of the residue should not exceed 0.005 Gm. (limit of *uncombined alkaloid*).

Actions and Uses.—Quinine tannate has the action of other salts of quinine but on account of its insolubility its action is less certain than the more soluble quinine salts. Its lack of bitterness renders it a suitable preparation for administration to children.

Dosage.—Inasmuch as quinine tannate contains but about half as much alkaloid as quinine sulphate its dose is proportionately greater.

Non-Proprietary Preparations:

Quinine tannate, N. Y. Q.—Manufactured by the New York Quinine and Chemical Works, New York, N. Y.

Quinine tannate, Brunswick.—Manufactured by the Brunswick Chemical Works, Brunswick, Germany (Mallinckrodt Chemical Works, St. Louis, Mo.).

Quinine tannate, P. W. R.—Manufactured by Powers-Weightman-Rosengarten Co., Philadelphia, Pa.

Therapeutics

PRESCRIPTION-WRITING

(Continued from page 1208)

CHAPTER III.—WEIGHTS AND MEASURES

It is not necessary to describe here the old system or to give its tables of weights and measures, as they occur in every book on prescription-writing, but some tables of approximate equivalents to the metric system will be offered. Exact equivalent tables are a delusion and only tend to befog and discredit the metric system. When it is remembered how the doses of drugs vary, it will be recognized how absurd it is to figure an equivalent to its finer determinations.

It is not necessary to declare that the decimal (metric) system of prescription-writing is the better, because the fact is recognized by all and the only hindrance to its use is the supposed difficulty of mastering it. Science of all countries and even our own Pharmacopeia has adopted it. If the novice in the use of the metric system in prescription-writing will remember that it is a decimal system like our monetary system, that everything on the left of the decimal point or line represents grams or cubic centimeters [dollars], that everything on the right of the decimal line represents centigrams, milligrams, or fractions of a cubic centimeter [cents and mills], he will soon understand the system. For instance:

		gm.
$1.25 or 1 gram and 25 centigrams	=	1.25
$1.001 or 1 gram and 1 milligram	=	1.001
$0.50 or ½ gram or 50 centigrams	=	.50
$0.05 or 5 centigrams...........	=	.05
$0.005 or 5 milligrams...........	=	.005
also		c.c.
$1.25 or 1¼ centimeters.........	=	1.25
$1.001 or 1 1/1000 centimeters....	=	1.001
$0.50 or ½ of a centimeter........	=	.50
$0.05 or 5/100 of a centimeter.....	=	.05
$0.005 or 5/1000 of a centimeter...	=	.005

In this country it is customary in writing prescriptions in the metric system to write for solids in terms of grams and fractions of grams, and for liquids in terms of cubic centimeters or fractions of cubic centimeters. The same decimal line which should be ruled on the prescription blank answers for both solid and liquid metric measures, and precludes all possibility of careless decimal mistakes, as:

gm.
c.c.

The following table is self-explanatory. It, as well as much other matter below, is taken from Osborne's "Introduction to Materia Medica and Pharmacology."

		gm.	
"A gram is written... 1.	gm. or	1.	and read 1 gram.
A decigram is written . 0.1	gm. or	.10	and read, best, 10 centigrams.
A centigram is written 0.01	gm. or	.01	and read 1 centigram.
A milligram is written. 0.001	gm. or	.001	and is read 1 milligram.
		c.c.	
A cubic centimeter is written 1 c.c.	or	1	and read 1 cubic centimeter.

As above declared, it is useless to translate the old system into exact equivalents of the new system. One must compute the doses in the new system: one must forget the size of stock bottles and order amounts of liquids in multiples of five, as 15 c.c., 25 c.c., 50 c.c., 100 c.c., or 200 c.c.; one must remember that 5 c.c. is a teaspoonful dose, i. e., an ordinary teaspoon holds 5 c.c. and not 4 c.c. or a liquid dram; in other words, *every* prescriber in the old system has *always* given a larger dose than he intended when he computed the dose by fluidrams and then administered a *teaspoonful; one* should remember that the drop, so much used in prescribing *strong liquid preparations*, is as correct in the new system as in the old. All of these suggestions must be followed out to use the metric system successfully.

TABLE OF THE APPROXIMATE EQUIVALENTS OF THE TWO SYSTEMS

	gm. c.c.	
1 grain (gr.i) = approximately...	0|065	= 65 milligrams = 1 grain.
1 minim (♏i) = approximately...	0|065	= 65/1000 of a cubic centimeter = 1 minim.
15 grains (gr.xv) = approximately.	1|	= 1 gram = 15 grains.
15 minims (♏xv) = approximately.	1|	= 1 cubic centimeter = 15 minims.
1 dram (ʒi) = approximately.....	4|	= 4 grains = 1 dram.

1 fluidram (fl.ʒi) = approximately 4 = 4 cubic centimeters = 1 fluidram.
1 ounce (℥i) = approximately.....30 = 30 grams = 1 ounce.
1 fluidounce (fl.℥i) = approximately.30 = 30 cubic centimeters = 1 fluidounce.
1 quart = approximately 1000 c.c., or 1 liter.
1 pint = approximately 500 c.c.
1 teaspoonful = approximately 5 c.c."

It is always a good plan to use a stub prescription blank, and on the stub the individual doses may be written. This is another check on mistakes and also preserves for reference the exact dose given on the exact date, as:

Stub (one dose)		Prescription for 20 doses	gm. c.c.		Old system
℞		℞			
Strych. sulph.	001	Strychninæ sulphatis..	02		gr.1/3
Ferri reducti.	05	Ferri reducti.........	1	or	gr.xv
Quin. sulph...	10	Quininæ sulphatis....	2		gr.xxx
M. et F. cap.		M. et F. capsulas 20.			
Sig.: t.i.d., p.c.		Sig.: A capsule 3 times a day, after meals.			
Name.					
Age.					
Date.					

Or,

Stub (one dose)		Prescription for 20 doses	gm. c.c. (approximately)		Old system

CHAPTER IV.—INCOMPATIBILITY

This is prevented only by great care and simplicity. Too many drugs should not be prescribed. Too many solutions should not be combined. Too many drugs and too much medicine should not be given to one patient on any one or two days. Many drugs are accumulative and many of their physiologic activities are antagonistic. Drugs may be incompatible *therapeutically, chemically and pharmaceutically.*

Therapeutic incompatibility occurs when drugs are combined which have antagonistic physiologic actions.

Chemical incompatibility occurs when from the combination of two or more drugs a new and undesired chemical compound results.

Pharmaceutic incompatibility occurs when drugs are combined which form, either immediately or later, cloudy, precipitated or decomposed solutions.

An educated physician should be ashamed to perpetrate a therapeutic incompatibility either in a prescription or in a patient. It is not therapeutic incompatibility, however, to modify a too decided action of a drug with one that corrects an undesired effect. This is a part of therapeutic science.

Pharmaceutical incompatibility is so closely related to chemical incompatibility that many times both are governed by the same rule. Such incompatibility is difficult to avoid, and therefore it is advisable to adopt simplicity in prescription-writing; this is really a therapeutic gain.

Below is given an alphabetical list of drugs comprising those that should generally be given alone, especially in solutions. The chemical reasons are appended:

Acids, unless very dilute and in small amount, should be prescribed alone. They combine with bases to form salts, and are incompatible with oxids, alkalies, alkaline salts, hydrates and carbonates. They all precipitate albumin.

Alkalies and alkaline carbonates should rarely be prescribed in solution with other drugs. They form salts with acids and precipitate many metallic and alkaloidal salts.

Alkaloidal salts should rarely be combined with other drugs in solutions. They are precipitated by alkalies, alkaline carbonates, earthy carbonates, preparations containing tannic acid, and by iodids in solution.

Antimony and potassium tartrate (tartar emetic) should be prescribed in solutions alone. It is incompatible with acids, alkalies, tannic acid, and preparations containing tannic acid.

Arsenic (arseni trioxidum, arsenious acid) should generally be prescribed in solutions alone.

It is precipitated by salts of iron, magnesia, and solutions of lime.

Bromids in solution should not be combined with alkaloids. They precipitate the salts of morphin, quinin, and strychnin from neutral solutions.

Ferric and ferrous salts should generally be prescribed alone. They are incompatible with tannic acid and all drugs containing it; with alkaline carbonates, ammonia, and acacia.

Iodids should generally be prescribed alone.

They are incompatible with salts of alkaloids and metals and with mineral acids.

Mercuric chlorid (corrosive sublimate) should generally be prescribed alone. It is incompatible with many drugs.

Mercurous chlorid (calomel), though insoluble, had best not be prescribed in mixtures. In solutions containing chlorids it may be converted into the mercuric salt.

Resins, including oleoresins, and fluidextracts and tinctures containing resins, should not be prescribed in watery solutions, though they may be ordered in emulsion by suspending them with the mucilage of acacia or tragacanth.

They are all precipitated by water.

Silver nitrate solutions and solutions of all silver salts must be ordered alone, and kept in dark bottles. If silver salts are prescribed for internal administration they must be alone or combined with some earth, and given in capsules.

Strophanthus in the form of the tincture should not be prescribed in solutions containing water.

It slowly forms a toxic substance, when in watery solution.

Spirits (spiritus), except sweet spirits of niter, whisky and brandy, should mostly not be prescribed with watery preparations. They become cloudy on the addition of water.

Tannic acid, and all drugs containing tannic acid, should not be prescribed with most drugs. They are incompatible with alkaloids, salts of iron, lead, silver and antimony.

ANAPHYLAXIS AND THE ONSET OF LABOR

The problem of the onset of labor has long been a favorite subject of conjecture, and of the theories invoked to explain it there is no end; hence it was to be expected that sooner or later the results of modern immunologic work would be brought to bear on this question. In a recent article, von der Heide[1] presents some experimental results and deductions from them, which apparently serve to explain the problem on this basis.

It had previously been observed in the case of twin girls, united like the classical Siamese twins, that during the pregnancy of one, the other as well showed the secondary symptoms; but that during parturition, the non-parturient felt no inconvenience. White rats artificially united to pregnant companions, on the other hand, suffered no disturbance until the onset of labor, when they became very sick and occasionally died. Those most likely to survive were found to be those united longest to their fellow. Inasmuch as such work pointed unmistakably toward the discharge of toxic substances with antigenic properties into the blood of the mother, with a presumable development of antibodies, von der Heide undertook to study the problem by means of the blood itself. His first work, consisting in the injection of blood from parturient women into women in advanced pregnancy, was without result. Thereupon he tried the injection of fetal blood in similar cases, and with this a certain proportion gave definite reactions. In four cases labor pains, previously absent, followed more or less directly after the injection of the serum, usually within three or four hours, and continued to delivery. In two instances, only 2 c.c. of serum were needed; in one, no result occurred until after a second injection. In three other cases, transitory pains followed; eight gave completely negative results. Injections during weakening pains in actual labor resulted in their renewal in six instances. The effect on the pains was usually preceded or accompanied by a transient rise in temperature and pulse-rate.

The explanation of these results, von der Heide believes, is to be sought in the direction of a gradual liberation of fetal products into the maternal circulation during pregnancy, and the formation of antibodies to these. Toward the end of pregnancy an excessive amount of this fetal antigen enters the mother's blood, and the reaction between this and the antibodies previously formed sets free labor-inducing substances, i. e., gives an anaphylactic reaction, resulting in the onset of labor.

Viewed in this light, it is easy to see why the injection of fetal blood should induce pains, while that of parturients would be without effect unless given in very large doses, because of the dilution of the fetal products in it. And while the symptoms of labor are by no means typical of anaphylactic shock, the conditions of sensitization and reaction would be different enough between the two to afford a satisfactory explanation of this. Incidentally, many of the minor phenomena of pregnancy point toward an anaphylactic condition—the frequency of urticaria, of albuminuria, of vomiting, the peculiar action of narcotics. Eclampsia itself has many of the features of acute anaphylactic shock.

It is, of course, too early to pass judgment on this theory in the light of our present limited knowledge both of anaphylaxis and of the causes underlying the onset of labor. Further work must be done to test its validity; but whether or not it will stand this test, it will at least have had the merit of bringing into the center of interest an obscure but important physiologic problem.

ANTIFAT AND SOCIETY WOMEN

Under the display heading "Antifat Drug a Peril: Many Newport Society Leaders Suffer From Using Preparation," an eastern newspaper prints the following "special" from Newport, R. I.: "Every now and then it is reported that a Washington, New York or Philadelphia or Boston or western woman, who has been a shining light in society here, is in bad health, and it is the proper thing to say she has broken down under the strain of her social duties. But it became known to-day that the poor health of some women who have broken down here has been caused by the use of a dangerous antifat drug, with which fashionable women in Europe first experimented. Women in Newport have been using this drug ever since fashion decreed that a truly fair one must be slender. So threatening have been the consequences of using it that these women have abandoned the drug. Physicians are treating them to restore the normal tone of their systems, and they gladly submit to medical treatment, even at the risk of regaining their stoutness."

It would be interesting to know the name of the "antifat" the ladies of this aristocratic colony are using. It is quite probable that it is one supplied by some of the mail-order quacks, the main ingredient of which is thyroid. This drug is so much more effective as a fat-reducer than any of the older ones that it has practically replaced the latter. But like most effective drugs it has its dangerous side. A few years ago when Germany placed strict restrictions on the sale of thyroid it was common gossip that this action was accelerated by the fact that some of the first ladies of that country had had an experience similar to that reported from Newport.

---

[1] Von der Heide, A.: München. med. Wchnschr., 1911, lviii, 1705; abstr. in The Journal, Sept. 29, 1911, page 1090.

Thyroid is stated to be used more extensively as an antifat than for any other purpose. It is used as such and, as some of the Washington officials have found, as an ingredient of many patent medicines. It would be well for physicians to make inquiries on this subject when consulted by obese patients complaining of sleeplessness, nervousness, palpitation, gastric disturbances, etc.; patients are not very likely to volunteer the information that they have been taking thyroid and still less that they have been patronizing some mail-order house. In fact, we have heard of patients who recognized that their troubles were due to a drug of this class and who thought it "a joke on the doctor" because he had not suspected it.

The use of thyroid in obesity is not only accompanied by a certain degree of danger, especially if the patient is not under constant medical supervision, but it is in most cases an illogical form of treatment. It is now recognized that it is unsafe to make any material reduction in the diet, except in the fat, during a course of treatment; otherwise there will be a loss of body protein as well as of fat, and a loss of protein seems to be closely associated with the untoward symptoms often observed. In other words, in a safe reduction cure by thyroid more food than the body needs is taken; this excess and some of the body's own fat is burned up under the influence of the thyroid. The organs are thus forced to do an unnecessary amount of work.

In diet cures, on the other hand, as Chittenden for example has shown, the diet may be greatly restricted (even to two-thirds of the body's requirements) and a considerable amount of fat lost without any danger to the body protein.

Although in most cases of obesity, treatment by thyroid is essentially illogical and treatment by diet and exercise logical, there will always be patients who will refuse to follow instructions as to the latter; in such cases and in certain others which do not yield readily to a diet-cure (cases of "constitutional obesity"), thyroid may be used, but it should never be placed in the patient's hands without careful supervision. Patients should also be warned that the fat will promptly return after the thyroid treatment unless they learn to regulate their diet and exercise properly, and emphasis should be laid on the fact that in almost every case the obesity is due simply to over-eating or to lack of exercise or to a combination of these.

VEGETABLE JELLIES AND MUCILAGES AS FOODS

The food-value of various mucilaginous and gelatinous plant substances has been highly appraised by the layman and by most physicians for untold years. In some countries, notably Japan, Turkey and Hawaii, such substances are staple articles of diet; in Scotland and Ireland the dulse is a favorite food. Clinicians have frequently tried various articles of this class, especially as substitutes for starches and sugar in diabetes; and Iceland moss is found in drug-stores as a standard article of commerce, being sometimes used as a delicacy for consumptives, who are expected to secure much benefit from its digestibility and its reputed high nutritive value. The United States Dispensatory itself goes on record to the effect that the mucilaginous extract of slippery elm bark, and also the Turkish salep, are highly nutritious. It is strange that, in spite of the prevalence of the use of lichens, algæ, and other gelatinous or mucilaginous vegetable substances as food, their real nutritive value has not received previously any serious investigation; hence a recent extensive study of ten articles of this class by Dr. Mary D. Swartz[1] is all the more to be appreciated.

Most of the carbohydrates of the vegetable substances under consideration belong to the hemicellulose group: that is, they are not converted into sugar by diastase, but are readily hydrolyzed by dilute acids. According to the sugars they yield on hydrolysis they are designated as pentosans, dextrans, mannans, galactans, etc. Thus agar-agar is a galactan, since it is composed of molecules of galactose united through dehydration and readily separated by hydration with acids; Irish moss also contains a galactan, while Iceland moss contains chiefly dextrans, dulse is rich in pentosans, and the gelatinous material of salep is a mannan. Cellulose itself is a dextran, and were it as readily hydrolyzed by the digestive enzymes as the starches it would be just as good a food. Unfortunately, at least from an economic standpoint, the human organism does not seem to be provided with enzymes capable of disintegrating cellulose, and so we rely on the hydrolysis by strong acids in the works of the glucose trust to render the fibrous cellulose into its assimilable sugar.

Only recently has the therapeutic importance of the utter indigestibility of some of the hemicelluloses been recognized, and whereas formerly agar-agar and similar substances were put on the market as "vegetable gelatins" of great value as foods, now the same things are sold as laxatives because they are not assimilated at all, and hence greatly increase the bulk and softness of the feces. Of the ten varieties of hemicellulose foods studied by Dr. Swartz, dulse and salep showed the highest utilization, both of these disappearing entirely from the contents of the *alimentary tract. Irish moss, however,* was passed out in the feces almost entirely, and the other preparations were recovered to the extent of 40 to 90 per cent. The partial utilization observed must be ascribed to alteration through bacterial action, since no good evidence could be obtained of the presence of diastase capable of digesting these hemicelluloses, and the several varieties disappeared from the intestine in direct ratio to their susceptibility to bacterial decomposition. Whether bacterial disintegration of hemicelluloses yields sugars or products which are utilized by the human body is still another question, to be determined only by careful study of respiratory exchange. In any case these investigations of the food-value of hemicelluloses indicate that most of the forms commonly used for food can give but little nourishment; possibly some varieties have a certain value, but it will be entirely unsafe to rely on one of them for any considerable part of the dietary of either sick or well, until careful investigations have established its actual food-value. With due appreciation of the limits of their nutritive value, they may, of course, be used as gelatinous or mucilaginous bases of food or drink, and as laxatives or as vehicles for drugs under proper conditions.

B.: Das Verhalten einiger unverdaulichen Kohlehydrate in Verdauungstrakt, Zentralbl. ges. Phys. u. Path. d. Stoffw., 1908, No. 17. Mendel, L. B., and Swartz, Mary D.: The Physiological Utilization of Some Complex Carbohydrates, Am. Jour. Med. Sc., March, 1910.

ERGOT AND THE MANUFACTURER OF PHARMACEUTICALS

Last week we commented on a bulletin just issued by the Public Health and Marine-Hospital Service on the standardization of ergot; this week, under "The Propaganda for Reform" we print the conclusions of this bulletin as they relate to the examination of a number of commercial preparations. Comments on these results are scarcely needed. They show again how little reliance can be placed on the statements of the "great manufacturing houses" in regard to their so-called "ethical" proprietaries and pharmaceutical "specialties." Of course, these houses will raise vigorous objections, doubtless similar to those raised to the reports on epinephrin and digitalis. Some "didn't know"; but they should have known before making such positive claims. All will doubtless complain that the preparations examined were few in number and were old. The preparations were few in number, as the authors state, but it is suggestive that not one of them approached the strength claimed. Possibly some were old, but they are claimed to be "permanent"; at any event they were obtained in the open market, under exactly the same conditions as those under which physicians obtain them every day. Some firms may even go to the length (or depth) that Parke, Davis and Co. did a year or two ago when the Hygienic Laboratory reported on one of their digitalis preparations—digitalone; a physician forwarded to THE JOURNAL a letter from this firm in which they said: "We have reason to suspect that these old samples were purposely selected for *the test." On that occasion, as on* this, the preparations were bought through the regular purchasing departments of the University of Michigan and of the Hygienic Laboratory, and there is certainly no reason for believing that these institutions would receive worse preparations than would a physician.

The plain truth is that although these large firms are perfectly able financially, and probably scientifically, to prepare trustworthy preparations, or if not, are able to learn how to do so, they show an indifference as long as they can sell their products. This strongly suggests that the biologic laboratories maintained by them are mainly for advertising purposes. Surely after several decades of experience they should have learned that their products are not "permanent" and should have adopted the simple and honest expedient of stating the date of manufacture on the label and the period during which the preparations could reasonably be expected to be of therapeutic value; they could have learned the conditions under which the preparations deteriorate and if these were controllable pharmacists could have been instructed accordingly. Yet the facts are that one of the chief claims made for practically all the proprietary preparations of ergot is that of permanency! As usually happens in such cases, the firms which lay the greatest stress on some particular quality of their proprietary preparations are the very ones whose products are found to be most lacking in that particular quality. So, in this instance, the firms whose claims for the permanency of their preparations are most conservative are the ones whose products come nearest to measuring up to the desired standard; while those concerns whose proprietaries are the least dependable are the ones that make the most vociferous claims for permanency and reliability.

The Council on Pharmacy and Chemistry was organized to help physicians discriminate between trustworthy and untrustworthy drugs, and manufacturers who had preparations which they were willing to have submitted to examination, for inclusion in New and Nonofficial Remedies, were invited to submit them to the Council. These studies again justify the distrust with which many of the better-informed physicians regard products which are not in New and Nonofficial Remedies.

Unfortunately the Food and Drugs Act in its present form does not permit the government to proceed against firms or individuals who place on the market misbranded drugs of this character; hence physicians are dependent on the work which their representatives on the Council on Pharmacy and Chemistry, in the Association Laboratory, and in the Hygienic Laboratory, can do for them. The Association proposes to continue this work; it also trusts that the Hygienic Laboratory will continue to help the physician and public by further work of this character and that its activities will not be hampered by lack of appropriations and by the kind of red tape which has temporarily *almost paralyzed* the Bureau of Chemistry of the Department of Agriculture.

Current Comment

INVIDIOUS COMPARISONS BY THE BORAX PEOPLE

The borax trust is still spending a good deal of money sending out letters through its press-agent, "H. L. Harris." At this time it is trying to offset the splendid tributes which the American press has paid to Dr. Wiley in the last few weeks. If this "Harris" letter went no further than to damn the Bureau of Chemistry and its chief, we should not take the trouble to refer to the borax people again. But incidentally it panegyrizes the Bureau of Animal Industry, the department that has charge of examining the meat-supplies of the country. And now comes the *National Provisioner* of New York, also unfriendly to Dr. Wiley, with a long editorial criticizing the chief of the Bureau of Chemistry and praising the Bureau of Animal Industry. The argument seems to be that while Dr. Wiley's bureau has not had a placid and uneventful career, the Bureau of Animal Industry runs on "without friction." As the public loves Dr. Wiley for the enemies he has made, so it will regard the Bureau of Animal Industry with suspicion on realizing who are the friends of that bureau. As a general proposition, any government department which stands between organized greed and the public health will inevitably develop "friction" if it works in the interest of the public. Conversely, when such a piece of governmental machinery is working without friction it behooves the public to inquire closely into the source that is furnishing the lubricant. It is not altogether true that the Bureau of Animal Industry has been free from criticism. It will be remembered that a year or so ago some ugly charges were preferred against some of the government officials in this department relative to the inefficient way in which the meat-supply at St. Louis was inspected. In this case, however, the criticism was not that the government was hurting "business interests," but that it was not giving the public the degree of protection against diseased meat for which that bureau is supposed to exist! All things considered, any invidious comparisons between the Bureau of Chemistry and the Bureau of Animal Industry will be likely to react to the detriment of the latter, whose chief may be tempted to cry: "Save me from my friends!"

THE TREATMENT OF RHUS POISONING

The publication in THE JOURNAL[1] of several communications on the treatment of ivy poisoning, and the inefficacy of the methods currently employed for the alleviation of this distressing condition, may justify reference to the properties of the toxic agent and a rational procedure to eliminate its effects. The leaves and flowers of the poison ivy plant yield a poisonous tar which is soluble in both alcohol and ether and has been extensively investigated by Acree and Syme[2] in Baltimore. The familiar method of treating the skin eruption consists in the use of an alcoholic solution of acetate of lead. This is most unsatisfactory, as Acree and Syme have pointed out, because the action of the remedy "consists in depositing an unstable lead salt of the poison in the skin, where the conditions of moisture and temperature are favorable for its decomposition, liberating the poison with all its irritant properties." There is great difficulty in reaching the poison which has permeated the skin (hence the presumable efficacy of the vigorous "scrubbing" advocated in one of the communications to THE JOURNAL[1]). One must assume, despite the reports alluded to, that the use of both alcohol and ether solutions is to be avoided, because they act as solvents and may thus serve to spread the poison over large areas—unless perhaps they are used in sufficient quantities to wash away the dissolved poison. A correspondent in this issue suggests the use of rubber gloves to avoid spreading the poison. Acree and Syme have found that potassium permanganate completely oxidizes the poison. This has furnished the basis for a rational method of treatment repeatedly tested and found by them to effect a speedy cure. The part affected is immersed in, or bathed with, a solution of potassium permanganate as hot as can easily be borne. Where the skin is broken, dilute solutions (1 per cent.) should be used; otherwise the concentration may be varied according to the location and condition of the eruption. A little dilute alkali or sulphuric acid is advantageously added to the permanganate solution; the oxidizing power is greater in the acid solution. In rare instances, when the poison is present deep in the skin, it should be exposed to the action of the permanganate for a considerable time. The dark stain produced by the permanganate will wear off or can be removed by vigorous scrubbing with soap; or it can be dispelled at once by a warm solution of oxalic acid (with due precaution). The extremely rare cases of systemic intoxication through entrance of the poison directly into the circulation obviously require special constitutional treatment.

WILL ILLINOIS BE EASY?

S. R. Chamlee, M.D., is a cancer-cure faker whom Samuel Hopkins Adams characterized as "a scoundrel who endeavors to frighten women into taking his treatment by advertising in the papers, 'in woman's breast any lump is cancer.'" For some years Chamlee carried on his nefarious trade at St. Louis, Missouri. Nemesis, in the form of post-office fraud order, finally overtook him and closed the mails to him.[1] He attempted to evade the law by changing the name of his business to the "St. Louis Sanitarium Company" and by instructing his prospective victims to send their money "through an express company" and not by post-office money order, because he could not cash the latter. The post-office extended its fraud order to the "St. Louis Sanitarium Company" and this irrepressible quack assumed another name, the "United Specialist Cancer Cure Company." The post-office, in time, still further extended its order. All this happened in the latter part of 1909. For a year or more the magazines and newspapers have been free from Chamlee's advertisements. Within the last month or two, however, Chamlee has again commenced advertising. But he has changed his headquarters; instead of operating from St. Louis he is now in Chicago. The advertising matter, "form letters," pamphlets, etc., that Chamlee now uses are apparently identical with those which he used in St. Louis. Chamlee has no license to practice in Illinois—although, we believe, he is licensed in Missouri and Iowa. For this reason, in order to keep within the law, it is necessary for him to employ some renegade physician who is licensed. This, apparently, he intends to do, for the following advertisement appeared in the Chicago *Tribune* a week ago:

---

[1] THE JOURNAL A. M. A., Sept. 30, 1911, p. 1151; Oct. 14, 1911, p. 1304.

[2] Acree and Syme: Jour. Biol. Chem., 1907, ii, 547.

[1] This case was referred to in THE JOURNAL A. M. A., Jan. 15, 1910, and a full account appears in "Nostrums and Quackery," page 31.

> PHYSICIAN — FINE LOOKING, NO OTHER, NO smoker; must be quite gray and move to Oak Park. Write fully with new photo, or call 36 W. Randolph St., Dr. Chamlee, Room 308.

Oak Park is a suburb of Chicago and, while Chamlee's mailing address is in the down-town district of Chicago, he sends out his "literature" from Oak Park. Chamlee is apparently just as big a fraud to-day as he was two years ago. The question arises: Will the federal authorities make things as interesting for him in Illinois as they did in Missouri?

NEWSPAPER ETHICS

The *Daily Tribune* is the name of a newspaper published in Goldfield, Nevada. A few days ago the *Tribune* received a letter from a notorious quack of Portland, Oregon, one T. J. Pierce, asking for quotations on two classified advertisements to appear in the personal column. One of the advertisements was of "Sexoid—a marvelous cure for weakness in men;" the other was for "Sanderson's Cotton Root Pills—safe and sure cure for delayed periods." Pierce doubtless imagined that in a mining community like Goldfield "everything goes" in the way of advertising; and he must have been surprised to learn from the business manager of the Goldfield *Tribune* that "the advertising in question does not conform to the policy of this newspaper in its advertising department." We commend the advanced and enlightened attitude of the Goldfield *Tribune* to several Eastern newspapers whose claims to culture are as pretentious as their business morality is inferior.

THE RIGHT OF SOCIETIES TO REGULATE MEMBERSHIP

In another department[1] appears an abstract of a recent decision by the Supreme Court of the State of New York, in the case of Ewald against the Medical Society of the County of New York, in which the court holds that a member of a medical society cannot by injunction prevent the society from trying him on charges preferred against him. In this case, after the charges were preferred, and before the trial, the plaintiff sent in his resignation, but as the by-laws of the society provided that no resignation could be accepted from a member under charges, the court held that the defendant society had a right to ignore the resignation and to proceed to discipline its member according to its by-laws. The court further says that a member joining a professional society assumes an obligation not only to conform to the rules of the society, but also to observe its standard of professional ethics, and that, having voluntarily become a member of such an organization, he is bound by his act to submit to its rules and conform to its standards. Practically, the decision in this case amounts to an affirmation of the right of a professional organization to enforce its professional standards, and to discipline its members, so long as it acts in accordance with its own by-laws and proceeds in a legal and orderly manner.

A NATIONAL DEPARTMENT OF HEALTH

In the Medical Economics Department of The Journal appears an extract from a recent editorial in *La Follette's Weekly*. The daily press, for several days past, has contained dispatches from Washington, regarding the efforts to be made at the coming session of Congress to secure the passage of Senator Owen's Senate Bill or some similar measure providing for a national department, or an independent bureau, of health. It seems fitting, at the present time, to call attention to a few errors into which, apparently, some persons and organizations have fallen regarding this proposed department of health. 1. The American Medical Association is not a "medical trust." To intelligent and thinking people, such a statement is not necessary. It is a national professional organization of scientific men, endeavoring to be of service to the people and to elevate the standard of medicine. It could not "establish a monopoly" of healing if it desired to do so, and it would not if it could. It would limit the right to care for the sick to those who have sufficient knowledge of the human body to assume such a responsibility with safety to the patient and the public. And in this aim it should have the support of all right-thinking people. 2. A national department of health would exist for the study and prevention of human diseases, and not for the treatment of individual patients. Many sincere but misinformed persons have opposed such action on the part of the federal government because they have not distinguished between disease and the person afflicted with the disease. A national department of health would study diseases, their cause, method of transmission and prevention, just as the Department of Agriculture investigates seeds, soils, crops and animal and vegetable diseases. It would have no more authority over the individual invalid than the Department of Agriculture now has over the individual farmer. 3. One of the favorite arguments made against a national department of health is that it would establish a "state school of medicine" and would limit the practice of medicine to a certain class. This argument, of course, is absurd. The establishment of a Department of Agriculture has not resulted in a state school of agriculture, nor has the establishment of a Department of Commerce and Labor brought about a state school of business or labor. Furthermore, every competent lawyer knows that the regulation and restriction of the practice of medicine, like that of any other profession or calling, is a function of the individual state and not of the national government. Congress has no right to say, and could not say, who shall or shall not practice medicine in Illinois or New York or California. Each state must settle this question as it sees fit. 4. The American Medical Association is not responsible for the bills recently introduced into the senate; they were prepared by Senator Owen, on his own initiative. The American Medical Association is naturally in favor of such a bill and will do all in its power to secure its passage, but the credit of originating it is due to Senator Owen. The American Medical Association has urged such legislation for over twenty years. It will continue to urge it and to do everything it can to secure it, now and in the future, until Congress shows the same regard and gives the same care to human life that it now gives to that of the animal, to crops and produce, to banks and business concerns, and to the innumerable material interests of the people which the federal government now safeguards. The objections urged against this measure are either figments of the imagination, held by sincere but misguided and prejudiced persons, or specious and fallacious objections raised by those having a selfish interest in the perpetuation of existing conditions. The misguided must be enlightened and the selfish objectors must be exposed. The more discussion there is on this important subject, the better. The more thoroughly the plan is understood, the clearer will its advantages be seen, and the sooner will it become a reality.

Medical News

ALABAMA

New Throat Clinic.—A free clinic for examinations of the throat will be held on Tuesday and Thursday afternoons from 2:30 o'clock, by Dr. William Grace Harrison, Birmingham, in charge of that branch of the work of the Birmingham Antituberculosis League at the dispensary of the league, Room 424, Chamber of Commerce Building. The dispensary is also open for the examination of tuberculosis patients on Mondays, Wednesdays and Fridays, from 1:30 to 2:30 p. m.

CALIFORNIA

Bubonic Plague Near Ripon.—M. E. Sawyer of the State Board of Health and Dr. George W. McCoy, U. S. P. H. and M.-H. Service, are said to have verified the diagnosis of the local physicians in the case of Angel O. Bianchi, suffering with bubonic plague, on the Brown ranch near Ripon.

Donation to Medical Library.—Announcement has been made by the board of trustees of Leland Stanford, Jr., University, Palo Alto, of a gift of $10,000 made by Dr. Adolph Barkan, San Francisco, professor emeritus of the medical school, for the establishment of a special library dealing with diseases of the eye, ear, nose and throat. A gift of $5,000 from Charles G. Stanford for medical library purposes was also announced.

Personal.—Dr. Eleanor C. Seymour, resident physician of the Pacific Hospital, Los Angeles, has been appointed bacteriologist in the state hygienic laboratory, Berkeley.——Dr. M. Antoinette Bennette, San Bernardino, superintendent of nurses at the Los Angeles County Hospital, has resigned.——Dr. Emil O. Jellinek, San Francisco, has returned from Europe.——Dr. Irving R. Bancroft, assistant health commissioner of Los Angeles, has resigned to become physician of the board of education.

COLORADO

Personal.—Dr. Mary E. Phelps, Canon City, has returned after a year abroad.——Dr. Frank B. Stephenson, Marble, has moved to Denver, and Dr. Minerva M. Knott, Canon City, has returned to her former location at Sedalia, Mo.

Milk Consumers Protected.—Milk consumers in Colorado will be protected by the publication of names of owners who refuse to have their cattle tested for tuberculosis. There is no law in the state providing for the condemnation of diseased animals

Public Drinking-Cup Removed.—The State Board of Health has ordered the removal of public drinking-cups from public school buildings in the state.

ILLINOIS

Personal.—Dr. Carl J. F. Rochow, Rock Island, has returned from Europe.——Dr. James Harry Pittman, Camp Point, while hunting, accidentally shot off one toe of his right foot.——Dr. Samuel M. Barnes, Fairbury, who is ill in St. Luke's Hospital, Chicago, is reported to be in critical condition.——Dr. John E. P. Butz, Potomac, who recently underwent a surgical operation at the Augustana Hospital, Chicago, is reported to be convalescent.

State Board Exhibit at State Fair.—The Illinois State Board of Health had an interesting and instructive exhibit at the state fair last week; a large electric sign in front of the booth which read as follows: "Every time a light goes out, some one in the civilized world dies from consumption—2 every minute, 120 every hour, 2,880 every day, 1,000,000 every year," and emphasized by the automatic extinguishment every thirty seconds of the red electric lamps which bordered the sign, conveyed graphically to visitors the frequency of deaths from tuberculosis. This was still further emphasized by the use of a doll changing into a skeleton every half minute. The exhibit also showed the contrast between sanitary and unsanitary rooms, the right and wrong way of disinfecting houses after contagious diseases, microscopic specimens, the means of transmission of typhoid fever, diphtheria, etc.

Chicago

Personal.—Dr. Anna Dwyer has been reelected high medical examiner of the Women's Catholic Order of Foresters.——Dr. and Mrs. Eugene S. Talbot and Dr. Harry Jackson have returned from Europe.

County Board Buys Hospital Site.—The Cook County Board on October 3 decided to purchase for an emergency hospital the property at 4431-33 South Halsted Street, improved with a three-story brick structure about ten years old.

"Typhoid-Carrier" Freed.—Miss Rosie E. Pell, the alleged typhoid-carrier, on October 2 was given a permit by the Chicago Health Department to return to the house of her stepfather, Gilbert Boersma, a dairy farmer at Mount Greenwood, who sells milk in Chicago. She goes back to the farm on the understanding that she is to have nothing to do with the handling of milk.

KANSAS

Personal.—Dr. W. L. Gleason has succeeded to the practice of Dr. Charles F. Kyser, Conway Springs. Dr. Kyser is reported to be seriously ill in St. Francis Hospital at Colorado Springs, Colo.——Dr. John D. Horne, Coffeyville, is confined to his home, as a result of cerebral hemorrhage.——Dr. George H. Matchette has been elected a director of the McPherson Hospital.——Fire in Greenleaf, September 5, destroyed the office of Dr. Z. Hosea Snyder, who suffered a loss of $5,000.——Dr. William W. Minick has been elected mayor of Wichita.——Dr. James Stewart has been appointed city physician of Topeka.——Dr. Ansel M. Edison, Topeka, has retired from practice and will make his home in La Porte, Tex.——Dr. Mortimer Marder, police surgeon of Kansas City, has resigned.

MARYLAND

Herter Memorial Meeting.—The medical faculty of the Johns Hopkins University and other friends met October 5 to commemorate the life and work of the late Dr. Christian A. Herter, New York City, who with his wife founded the Herter lectureship.

Baltimore

Home from Europe.—Drs. James J. Mills, William S. Thayer, Joseph E. Gichner and Lewellys F. Barker have returned from Europe.

Typhoid Vaccin Adopted.—Typhoid vaccin is to be used in the state institutions by decision of the state board of health published October 5.

Kossel Entertained.—At the conclusion of the Herter lectures Dr. Albrecht Kossel was entertained at dinner at the Maryland Club by Dr. William H. Welch. About twenty members of the faculty of the Johns Hopkins school were present. Dr. and Mrs. Kossel will sail for Europe October 24.

Personal.—Dr. James H. Bay has been appointed by the postoffice department as examining physician to the civil service board of examiners for Havre de Grace.——Dr. Eugene Wright has succeeded Dr. Don P. Peters as superintendent tising. But he has changed his headquarters; instead of operating from St. Louis he is now in Chicago. The advertising matter, "form letters," pamphlets, etc., that Chamlee now uses are apparently identical with those which he used in St. Louis. Chamlee has no license to practice in Illinois—although, we believe, he is licensed in Missouri and Iowa. For this reason, in order to keep within the law, it is necessary for him to employ some renegade physician who is licensed. This, apparently, he intends to do, for the following advertisement appeared in the Chicago *Tribune* a week ago:

> PHYSICIAN — FINE LOOKING, NO OTHER, NO smoker; must be quite gray and move to Oak Park. Write fully with new photo, or call 36 W. Randolph St., *Dr. Chamlee, Room 308.*

Oak Park is a suburb of Chicago and, while Chamlee's mailing address is in the down-town district of Chicago, he sends out his "literature" from Oak Park. Chamlee is apparently just as big a fraud to-day as he was two years ago. The question arises: Will the federal authorities make things as interesting for him in Illinois as they did in Missouri?

NEWSPAPER ETHICS

The *Daily Tribune* is the name of a newspaper published in Goldfield, Nevada. A few days ago the *Tribune* received a letter from a notorious quack of Portland, Oregon, one T. J. Pierce, asking for quotations on two classified advertisements to appear in the personal column. One of the advertisements was of "Sexoid—a marvelous cure for weakness in men;" the other was for "Sanderson's Cotton Root Pills—safe and sure cure for delayed periods." Pierce doubtless imagined that in a mining community like Goldfield "everything goes" in the way of advertising; and he must have been surprised to learn from the business manager of the Goldfield *Tribune* that "the advertising in question does not conform to the policy of this newspaper in its advertising department." We commend the advanced and enlightened attitude of the Goldfield *Tribune* to several Eastern newspapers whose claims to culture are as pretentious as their business morality is inferior.

THE RIGHT OF SOCIETIES TO REGULATE MEMBERSHIP

In another department[1] appears an abstract of a recent decision by the Supreme Court of the State of New York, in the case of Ewald against the Medical Society of the County of New York, in which the court holds that a member of a medical society cannot by injunction prevent the society from trying him on charges preferred against him. In this case, after the charges were preferred, and before the trial, the plaintiff sent in his resignation, but as the by-laws of the society provided that no resignation could be accepted from a member under charges, the court held that the defendant society had a right to ignore the resignation and to proceed to discipline its member according to its by-laws. The court further says that a member joining a professional society assumes an obligation not only to conform to the rules of the society, but also to observe its standard of professional ethics, and that, having voluntarily become a member of such an organization, he is bound by his act to submit to its rules and conform to its standards. Practically, the decision in this case amounts to an affirmation of the right of a professional organization to enforce its professional standards, and to discipline its members, so long as it acts in accordance with its own by-laws and proceeds in a legal and orderly manner.

A NATIONAL DEPARTMENT OF HEALTH

In the Medical Economics Department of The Journal appears an extract from a recent editorial in *La Follette's Weekly.* The daily press, for several days past, has contained dispatches from Washington, regarding the efforts to be made at the coming session of Congress to secure the passage of Senator Owen's Senate Bill or some similar measure providing for a national department, or an independent bureau, of health. It seems fitting, at the present time, to call attention to a few errors into which, apparently, some persons and organizations have fallen regarding this proposed department of health. 1. The American Medical Association is not a "medical trust." To intelligent and thinking people, such a statement is not necessary. It is a national professional organization of scientific men, endeavoring to be of service to the people and to elevate the standard of medicine. It could not "establish a monopoly" of healing if it desired to do so, and it would not if it could. It would limit the right to care for the sick to those who have sufficient knowledge of the human body to assume such a responsibility with safety to the patient and the public. And in this aim it should have the support of all right-thinking people. 2. A national department of health would exist for the study and prevention of human diseases, and not for the treatment of individual patients. Many sincere but misinformed persons have opposed such action on the part of the federal government because they have not distinguished between disease and the person afflicted with the disease. A national department of health would study diseases, their cause, method of transmission and prevention, just as the Department of Agriculture investigates seeds, soils, crops and animal and vegetable diseases. It would have no more authority over the individual invalid than the Department of Agriculture now has over the individual farmer. 3. One of the favorite arguments made against a national department of health is that it would establish a "state school of medicine" and would limit the practice of medicine to a certain class. This argument, of course, is absurd. The establishment of a Department of Agriculture has not resulted in a state school of agriculture, nor has the establishment of a Department of Commerce and Labor brought about a state school of business or labor. Furthermore, every competent lawyer knows that the regulation and restriction of the practice of medicine, like that of any other profession or calling, is a function of the individual state and not of the national government. Congress has no right to say, and could not say, who shall or shall not practice medicine in Illinois or New York or California. Each state must settle this question as it sees fit. 4. The American Medical Association is not responsible for the bills recently introduced into the senate; they were prepared by Senator Owen, on his own initiative. The American Medical Association is naturally in favor of such a bill and will do all in its power to secure its passage, but the credit of originating it is due to Senator Owen. The American Medical Association has urged such legislation for over twenty years. It will continue to urge it and to do everything it can to secure it, now and in the future, until Congress shows the same regard and gives the same care to human life that it now gives to that of the animal, to crops and produce, to banks and business concerns, and to the innumerable material interests of the people which the federal government now safeguards. The objections urged against this measure are either figments of the imagination, held by sincere but misguided and prejudiced persons, or specious and fallacious objections raised by those having a selfish interest in the perpetuation of existing conditions. The misguided must be enlightened and the selfish objectors must be exposed. The more discussion there is on this important subject, the better. The more thoroughly the plan is understood, the clearer will its advantages be seen, and the sooner will it become a reality.

Medical News

ALABAMA

New Throat Clinic.—A free clinic for examinations of the throat will be held on Tuesday and Thursday afternoons from 2:30 o'clock, by Dr. William Grace Harrison, Birmingham, in charge of that branch of the work of the Birmingham Anti-tuberculosis League at the dispensary of the league, Room 424, Chamber of Commerce Building. The dispensary is also open for the examination of tuberculosis patients on Mondays, Wednesdays and Fridays, from 1:30 to 2:30 p. m.

CALIFORNIA

Bubonic Plague Near Ripon.—M. E. Sawyer of the State Board of Health and Dr. George W. McCoy, U. S. P. H. and M.-H. Service, are said to have verified the diagnosis of the local physicians in the case of Angel O. Bianchi, suffering with bubonic plague, on the Brown ranch near Ripon.

Donation to Medical Library.—Announcement has been made by the board of trustees of Leland Stanford, Jr., University, Palo Alto, of a gift of $10,000 made by Dr. Adolph Barkan, San Francisco, professor emeritus of the medical school, for the establishment of a special library dealing with diseases of the eye, ear, nose and throat. A gift of $5,000 from Charles G. Stanford for medical library purposes was also announced.

Personal.—Dr. Eleanor C. Seymour, resident physician of the Pacific Hospital, Los Angeles, has been appointed bacteriologist in the state hygienic laboratory, Berkeley.——Dr. M. Antoinette Bennette, San Bernardino, superintendent of nurses at the Los Angeles County Hospital, has resigned.——Dr. Emil O. Jellinek, San Francisco, has returned from Europe.——Dr. Irving R. Bancroft, assistant health commissioner of Los Angeles, has resigned to become physician of the board of education.

COLORADO

Personal.—Dr. Mary E. Phelps, Canon City, has returned after a year abroad.——Dr. Frank B. Stephenson, Marble, has moved to Denver, and Dr. Minerva M. Knott, Canon City, has returned to her former location at Sedalia, Mo.

Milk Consumers Protected.—Milk consumers in Colorado will be protected by the publication of names of owners who refuse to have their cattle tested for tuberculosis. There is no law in the state providing for the condemnation of diseased animals

Public Drinking-Cup Removed.—The State Board of Health has ordered the removal of public drinking-cups from public school buildings in the state.

ILLINOIS

Personal.—Dr. Carl J. F. Rochow, Rock Island, has returned from Europe.——Dr. James Harry Pittman, Camp Point, while hunting, accidentally shot off one toe of his right foot.——Dr. Samuel M. Barnes, Fairbury, who is ill in St. Luke's Hospital, Chicago, is reported to be in critical condition.——Dr. John E. P. Butz, Potomac, who recently underwent a surgical operation at the Augustana Hospital, Chicago, is reported to be convalescent.

State Board Exhibit at State Fair.—The Illinois State Board of Health had an interesting and instructive exhibit at the state fair last week; a large electric sign in front of the booth which read as follows: "Every time a light goes out, some one in the civilized world dies from consumption—2 every minute, 120 every hour, 2,880 every day, 1,000,000 every year," and emphasized by the automatic extinguishment every thirty seconds of the red electric lamps which bordered the sign, conveyed graphically to visitors the frequency of deaths from tuberculosis. This was still further emphasized by the use of a doll changing into a skeleton every half minute. The exhibit also showed the contrast between sanitary and unsanitary rooms, the right and wrong way of disinfecting houses after contagious diseases, microscopic specimens, the means of transmission of typhoid fever, diphtheria, etc.

Chicago

Personal.—Dr. Anna Dwyer has been reelected high medical examiner of the Women's Catholic Order of Foresters.——Dr. and Mrs. Eugene S. Talbot and Dr. Harry Jackson have returned from Europe.

County Board Buys Hospital Site.—The Cook County Board on October 3 decided to purchase for an emergency hospital the property at 4431-33 South Halsted Street, improved with a three-story brick structure about ten years old.

"Typhoid-Carrier" Freed.—Miss Rosie E. Pell, the alleged typhoid-carrier, on October 2 was given a permit by the Chicago Health Department to return to the house of her stepfather, Gilbert Boersma, a dairy farmer at Mount Greenwood, who sells milk in Chicago. She goes back to the farm on the understanding that she is to have nothing to do with the handling of milk.

KANSAS

Personal.—Dr. W. L. Gleason has succeeded to the practice of Dr. Charles F. Kyser, Conway Springs. Dr. Kyser is reported to be seriously ill in St. Francis Hospital at Colorado Springs, Colo.——Dr. John D. Horne, Coffeyville, is confined to his home, as a result of cerebral hemorrhage.——Dr. George H. Matchette has been elected a director of the McPherson Hospital.——Fire in Greenleaf, September 5, destroyed the office of Dr. Z. Hosea Snyder, who suffered a loss of $5,000.——Dr. William W. Minick has been elected mayor of Wichita.——Dr. James Stewart has been appointed city physician of Topeka.——Dr. Ansel M. Edison, Topeka, has retired from practice and will make his home in La Porte, Tex.——Dr. Mortimer Marder, police surgeon of Kansas City, has resigned.

MARYLAND

Herter Memorial Meeting.—The medical faculty of the Johns Hopkins University and other friends met October 5 to commemorate the life and work of the late Dr. Christian A. Herter, New York City, who with his wife founded the Herter lectureship.

Baltimore

Home from Europe.—Drs. James J. Mills, William S. Thayer, Joseph E. Gichner and Lewellys F. Barker have returned from Europe.

Typhoid Vaccin Adopted.—Typhoid vaccin is to be used in the state institutions by decision of the state board of health published October 5.

Kossel Entertained.—At the conclusion of the Herter lectures Dr. Albrecht Kossel was entertained at dinner at the Maryland Club by Dr. William H. Welch. About twenty members of the faculty of the Johns Hopkins school were present. Dr. and Mrs. Kossel will sail for Europe October 24.

Personal.—Dr. James H. Bay has been appointed by the postoffice department as examining physician to the civil service board of examiners for Havre de Grace.——Dr. Eugene Wright has succeeded Dr. Don P. Peters as superintendent of the Church Home and Infirmary.——Dr. J. George Schmetzer is ill with typhoid fever at the Union Protestant Infirmary.——Dr. George J. Heuer has succeeded Dr. Charles M. Remsen, resigned, as resident surgeon at Johns Hopkins Hospital.——Dr. H. Ross Coppage has been appointed a member of the public bath commission.——Dr. B. Merrill Hopkinson, after twenty-one years service as soloist and choirmaster of Brown Memorial Church, has resigned. He was given a purse of gold by the congregation as a testimonial.

MASSACHUSETTS

Ether Day.—The sixty-fifth anniversary of Ether Day will be celebrated by appropriate exercises at the Massachusetts General Hospital, Boston, October 16. The address of the occasion will be delivered by Dr. Simon Flexner, New York City.

Personal.—Dr. George G. Bailey, Ipswich, has been appointed medical examiner of Essex County.——Dr. Ernest B. Emerson, superintendent of the North Reading State Sanitarium, has been appointed medical director of the state farm at Bridgewater, vice Dr. Alfred Elliott, retired.——Dr. David F. Atwater, Springfield, is said now to be the oldest alumnus of Yale College.

Council Meets.—At the stated meeting of the Council of the Massachusetts Medical Society, October 4, Drs. Charles F. Caney, Greenfield, and Justus G. Hanson, Northampton, were appointed delegates to the Vermont State Medical Society, and Drs. Lyman A. Jones, North Adams, and Richard S. Benner, Springfield, delegates to the Medical Society of the State of New York, and Dr. Percy E. Brown, Boston, was appointed a delegate to the Medical Society of Virginia. Dr. Horace D. Arnold, Boston, presented the report of the delegates to the American Medical Association and Dr. Harold C. Ernst, Boston, reported for the committee on state and national legislation the contemplated efforts to raise the standard of applicants for registration in medicine and hoped thereby that "Massachusetts may be lifted from its deplorable condition in this matter, in which it is so far behind, practically, almost all the states in the Union."

MINNESOTA

Personal.—Dr. Robert O. Earl, St. Paul, has returned from Europe.——Dr. John J. Eklund, Duluth, has resigned as a member of the State Board of Visitors.

Rush Alumni Meeting.—In connection with the annual meeting of the State Medical Association in St. Paul, the alumni of Rush Medical College, resident in Minnesota, held a meeting at which Dr. Bertram W. Sippy, Chicago, was the guest of honor. Dr. William H. Rowe, St. James, was elected president: Dr. T. C. Masters, Sauk Center, vice-president, and Dr. Bayley, Lake City, secretary.

State Medical Association Meeting.—The annual meeting of the Minnesota State Medical Association was held in St. Paul, October 4-6, and the following officers were elected: Dr. Haldor Sneve, St. Paul, president; Drs. Olaf T. Sherping, Fergus Falls, and William F. Wilson, Lake City, vice-presidents; Dr. Thomas S. McDavitt, St. Paul, secretary, reelected, and Dr. Richard J. Hill, Minneapolis, treasurer, reelected. It was decided to hold the next annual meeting at Duluth, Minn.

MISSOURI

Personal.—Dr. William S. Saunders, Clarence, is reported to be seriously ill.——Dr. John H. George, Leeds, has succeeded Dr. Addison M. Harrison, Lees Summit, as superintendent of the Jackson County Poor Farm.——Dr. John J. Farrell, Hannibal, has been elected secretary of the Marion County Board of Health.——Dr. and Mrs. George S. Drake, Jr., St. Louis, have returned from Europe.——Dr. Heine Marks, St. Louis, who has been seriously ill with septicemia, is reported to be improving.

St. Louis

New Milk Ordinance.—The Civic League has prepared an ordinance creating the position of chief milk inspector with a corps of assistant inspectors giving them power to inspect all dairies that furnish milk for consumption in St. Louis; providing for a system of licensing dairies by the board of health; and establishing a standard of ingredients. The proposed ordinance was of course vigorously opposed by the milk dealers, they claiming that it would give too much authority to the inspector and would compel a rise in the price of milk to 12 cents a quart. The bill in its present or a modified form will be introduced in the municipal assembly by the board of health.

NEW YORK

Personal.—Dr. Arthur J. Bedell, Albany, has returned after a trip from Japan, Siberia, Russia and England.——Dr. Roy L. Leak of the Ogdensburg State Hospital has been appointed second assistant physician at the Matteawan State Hospital and Dr. William J. Tiffany, who has been on temporary duty in that institution, has returned to the Binghamton State Hospital.

District Society Meeting.—At the annual meeting of the Eighth District Branch of the Medical Society of the State of New York, held in Dunkirk, September 26 and 27, the following officers were elected: president, Dr. Henry A. Eastman, Jamestown; vice-presidents, Dr. Arthur G. Bennett, Buffalo, and Dr. Carl G. Leo-Wolf, Niagara Falls; secretary, Dr. Carl S. Tompkins, Buffalo, and treasurer, Dr. Charles A. Wall, Buffalo.

State to Teach Hygiene.—The New York State Health Department has completed plans for giving a series of public health lectures in every important city and town in the state. Lectures on the following subjects will be included in the course: tuberculosis, typhoid fever, diphtheria, smallpox and vaccination; rabies, the value of vital statistics; carriers of disease; preventable diseases; the sanitation of a country home; sewage disposal; water filtration, and oral hygiene.

New York City

New Laboratory for Hospital.—A new research laboratory is to be added to the Roosevelt Hospital through the munificence of Mrs. E. H. Harriman. The laboratory will do special work in physiologic chemistry. Its erection will be under the charge of Dr. Lewis R. Morris.

New York University Debt Free.—On October 2 the last $20,000 was paid on a mortgage of $175,000 on the medical school of the New York University, thus leaving the property of the university debt free. The payment of this indebtedness was made possible by the bequest of John S. Kennedy.

Secret Division of Fees.—At the stated meeting of the New York Academy of Medicine, held October 6, it was unanimously carried that the secret division of fees was an evil; if any member of the Academy of Medicine was found guilty of this practice it should furnish sufficient grounds either for a demand for his resignation or to make him liable to expulsion.

Low Death Record.—The number of deaths reported in New York City during the nine months ended September 30 was 58,144, equivalent to a death-rate of 15.56 per 1,000, which compares favorably with the corresponding period of 1910, when the death-rate was 16.27. The average number of deaths for the first nine months of the preceding thirteen years was 18.77 per 1,000. The reduction in the death-rate of infants under 1 year of age was most marked during this period, as 11,733 deaths were reported, or 124.6 per 1,000 as compared with 12,922 deaths, or a rate of 142.3 per 1,000 during the corresponding period of last year. This is equivalent to a reduction of 17.7 per 1,000, or a saving of 1,667 lives of infants during the first 9 months of the year.

Health Day at the Budget Show.—October 5 was health day at the city budget show and much interest was shown in the exhibit of the department of health. In his address on this occasion the health commissioner stated that he was going to ask for $1,564,178 additional for his department next year. It is his intention to establish seventy-three milk depots in the city instead of the fifteen now operated by the department. He also intends to increase the corps of school nurses and to establish six school clinics, to provide additional dentists, and to extend the inspection of school children for contagious diseases and physical defects to all free schools, bringing under the supervision of the department nearly 900,000 children. The interest shown in the budget exhibit has made it seem advisable to install a permanent exhibit open at all times to the public in the new building of the health department at Center and Walker streets.

OHIO

State Health Authorities to Meet.—The Ohio State Board of Health announces that its thirty-first conference with representatives of local boards of health will be held October 19 and 20.

Refuses to Contribute.—The board of Stark County Commissioners, Canton, it is said, has refused to appropriate $7,976, its additional share, necessary for the completion of the tuberculosis hospital at Springfield Lake. Other counties in the compact have agreed to the increased cost, and the

MEDICAL NEWS

five-county tuberculosis hospital board has entered suit to compel the commissioners of Stark County to make this appropriation.

Personal.—Dr. Howard H. Herman, Dayton, has returned from Europe.——Dr. Carl H. Lund, Marietta, formerly a member of the medical staff of the Queen Copper Company, Douglas, Ariz., sailed for Europe, September 28.——Dr. John W. Clark, physician to the state penitentiary, Columbus, will hereafter attend to the duties formerly performed by Dr. A. J. Shoemaker, day physician.——Dr. Robert D. Gibson, Youngstown, is reported to be seriously ill at Mercy Hospital, Canton, as the result of an automobile accident.——Dr. George P. Buffett has been appointed ward physician of Cleveland, vice Dr. Frank W. Hickin, resigned.

Cincinnati

Personal.—Dr. Ernst Gustav Zinke was elected secretary of the American Association of Obstetricians and Gynecologists, at its twenty-fourth annual meeting, September 28.——Dr. and Mrs. Derrick T. Vail and family have returned from Europe.——Dr. Clayton B. Conwell, superintendent of the Ohio State Sanatorium for the Cure and Prevention of Tuberculosis, Mount Vernon, has resigned.

OREGON

New Faculty Members.—Announcement is made by Dr. Simeon E. Josephi, president of the medical department of the University of Oregon, Portland, of the following additions and changes in the faculty of the department: Dr. Franklin C. McLean of Chicago has been made professor of materia medica and pharmacology; Dr. Richard Dillehunt, also of Chicago, is to be lecturer in anatomy. Dr. Oscar T. Roberg, at present professor of anatomy, has been appointed professor of pathology, succeeding Dr. Robert C. Yenney, Portland, who has been made professor of clinical medicine.

Personal.—Dr. Thomas W. Ross, Astoria, has gone to Europe.——Dr. Cortez H. Wheeler has been reappointed health officer of Portland, and Dr. Samuel M. Gellert, assistant. ——Dr. Ferdinand H. Dammasch, assistant health officer of Portland, has gone to Europe.——Dr. Otis C. Hollister, Portland, was run down by an automobile recently and was seriously injured.——Dr. Theodore Fessler, Portland, has been elected great sachem of the Improved Order of Redmen for Oregon, vice Dr. Frank H. Vincil, Rosenburg, great chief of records, who has temporarily filled the position.——Dr. George S. Whiteside, Portland, secretary of the state medical association, was seriously injured in a polo game, September 18.——Dr. A. E. Rockey, Portland, who was operated on eight weeks ago for appendicitis, has recovered and resumed practice.——Dr. J. Chris O'Day, Portland, has returned after a brief vacation in the Cascades.

PENNSYLVANIA

Personal.—Dr. Samuel N. Traver, Steelton, sailed for the Mediterranean, September 30.——Drs. Luther B. Kline, Catawissa, and Milton H. Fussell, Philadelphia, were elected delegates to the American Medical Association by the Medical Society of the State of Pennsylvania at its recent meeting.

Relief for Flood Sufferers.—A letter has been received by The Journal, suggesting that a relief fund be opened for the benefit of the medical men who have suffered damage or destruction of their property by the recent flood at Austin. The secretary of the Medical Society of the State of Pennsylvania states that contributions for this purpose may be sent to Dr. Owen M. Shreve, Erie.

New Work for Assistant Secretary.—At the meeting of the House of Delegates of the Medical Society of the State of Pennsylvania, September 25, an amendment to the by-laws proposed by the committee on permanent location was adopted whereby the assistant secretary is henceforth to carry out all business details incident to the annual sessions of the society, under the advice and direction of the board of trustees.

Philadelphia

Election of Officers.—The new officers of the Medical Society of the Woman's Hospital for 1911-12 are: president, Dr. Florence E. Kraker; vice-president, Dr. Mary Buchanan; secretary, Dr. M. Louise Diez, and treasurer, Dr. Mary Thomas Miller.

Pediatric Joint Meeting in New York.—A joint meeting of the New England Pediatric Society, the Section on Pediatrics of the New York Academy of Medicine and the Philadelphia Pediatric Society, will be held in New York City on November 9. The entire day will be spent in visiting New York hospitals and a scientific meeting will follow at which three papers will be read, one by a member of each society.

Personal.—Dr. Andrew H. Woods, assistant neurologist to the Philadelphia Hospital, has been made vice-president of the Canton Christian College in China.——Dr. Marcus A. Franklin has returned from Europe.——Dr. Joseph Leidy, Jr., will sail for Europe on October 18.——At a meeting of the College of Physicians, October 5, the Alvarenga prize, valued at $180, was awarded to Dr. Francis D. Patterson for his thesis on "Parathyroid Glandules."

Tuberculosis Day Camp to Remain Open.—The results of the Tuberculosis Day Camp on the Delaware River front have been so gratifying that it will be kept open during October and very probably November also. The regime at the camp conforms strictly to that of a sanatorium and suitable cases, namely indigent tuberculosis patients, not requiring absolute rest in bed, may be referred by any physician and remain under his care, but must apply for a card of admission to the Tuberculosis Dispensary of the State Department of Health. The camp is a philanthropic enterprise, the funds for its support having been raised in response to an appeal sent out last spring by Dr. Joseph S. Neff, the honorary director, Mr. Edward B. Smith, treasurer, and Dr. Albert P. Francine, director.

GENERAL

Ohio Valley Physicians to Meet.—The thirteenth annual meeting of the Ohio Valley Medical Association will be held at Evansville, November 8 and 9, under the presidency of Dr. William D. Haines, Cincinnati.

Child-Savers to Meet.—The American Association for the Study and Prevention of Infant Mortality will hold a meeting at Hotel La Salle, Chicago, November 16 to 18, when the results of the recent European tour of investigation of Prof. Charles R. Henderson, of the University of Chicago, will be given.

Hookworm Conference.—The second annual conference on hookworm was held in Nashville, Tenn., September 15 and 16, and Little Rock was decided on as the place for the next conference in 1912. Dr. John A. Ferrell, Kenansville, N. C. was elected president, and Dr. William W. Dinsmore, Decatur, Ala., secretary of the conference.

Railway Surgeons Meet.—At the seventeenth annual meeting of the Big Four Railway Surgeons, held in Indianapolis, October 3, the following officers were elected: president, Dr. John H. Miller, Pana, Ill.; vice-presidents, Drs. William J. Means, Columbus, O.; John C. Sexton, Rushville, Ind., and John C. Epperson, Kansas, Ill.; and secretary-treasurer, Dr. Leonard A. Ensminger, Indianapolis (reelected).

Personal.—Captain John S. Lambie, Jr., M.C., U. S. Army, who was operated on at Johns Hopkins Hospital, September 22, for appendicitis, is reported to be doing well.——Colonel William W. Gray, M.C., U. S. Army, medical supply officer at the Presidio, San Francisco, was thrown from his horse in Golden Gate Park, September 16, fracturing several ribs and sustaining internal injuries.——Dr. Mary Eddy, medical missionary in Turkey, who has established two sanatoriums for consumptives, one near Beirut, and the other on Mount Lebanon, is making a two months' visit and lecture tour of the United States, to endeavor to secure medical supplies and funds to increase the scope of her tuberculosis work in Turkey.

Mississippi Valley Medical Association.—The annual meeting of the Mississippi Valley Medical Association, to be held in Nashville, October 17 to 19, promises to be one of the most interesting from a scientific standpoint of any in the history of the organization. Dr. Joseph D. Bryant, New York City, is to deliver the address on surgery, and Dr. James C. Wilson, Philadelphia, the address on medicine; the presidential address by Dr. Robert H. Babcock, Chicago, will be on "Medical Tendencies." The surgeon general of the U. S. P. H. & M.-H. Service has detailed Assistant Surgeon R. M. Grimm to attend the conference and present a paper on pellagra, and Surgeon William Colby Rucker to describe the work done by the public health service in the stamping out of bubonic plague. There is also to be a symposium on visceroptosis, which will be considered from all standpoints. In this Drs. Cornelius W. Suckling and William Billington of Birmingham, England, will participate. The entertainment provided for the association includes an automobile excursion to the Hermitage, the home of General Jackson, with an address by Dr. John A. Witherspoon, Nashville, Tenn., on "Old Hickory."

Appeal for John Morgan Monument.—A committee consisting of Edgar Fahs Smith, Ph.D., Dr. S. Weir Mitchell, Philadelphia, Sir William Osler, and Drs. William Pepper, Clarence Payne Franklin, and Swithin Chandler, Philadelphia, has been appointed to take up the project of erecting a fitting monument to John Morgan, founder of the first medical school in the United States, and director general of the hospitals and physician-in-chief of the American Army during the revolutionary war. He received his A.B. degree from the University of Pennsylvania in 1757, his M.D. from the University of Edinburgh; and later became L.R.C.P., Lond., and F.R.S. He was one of the founders of the College of Physicians of Philadelphia. In 1765 he persuaded the trustees of the College of Philadelphia to organize the first medical school in America, and in this institution he was a professor for three years. He died Oct. 15, 1789, and is buried in St. Peter's Church, Philadelphia, but no monument marks the place where his remains repose. The committee hopes that the medical profession in general in the United States, and all who, directly or indirectly, have owed anything to medical education, will heartily approve of this movement, to honor the name of John Morgan by an appropriate monument, marking his last resting place.

FOREIGN

Original of Sherlock Holmes Dies.—Dr. Joseph Bell, eminent surgeon of Edinburgh, said to have been the original of Sir Arthur Conan Doyle's famous character, Sherlock Holmes, died at his home in Midlothian, October 4, aged 74. Dr. Bell was formerly president of the Royal Medical Society of Edinburgh and of the Medico-Chirurgical Society, consulting surgeon to the Royal Infirmary, and Royal Hospital for Sick Children; demonstrator of anatomy in the university, and was for twenty-three years editor of the *Edinburgh Medical Journal*. He was an enthusiast in the study of mysterious crimes and gave to his student Conan Doyle his first insight into the wonderful possibilities of arriving at facts by the so-called deductive method.

LONDON LETTER

(From Our Regular Correspondent)

LONDON, Sept. 23, 1911.

The National Insurance Bill and the Question of Friendly Society Control

The national insurance bill is still in committee stage in the House of Commons. The passage of amendments of its medical part, rendering it more acceptable to the profession, has been described in previous letters to THE JOURNAL, but the struggle is by no means over. The British Medical Association is continuing to organize the profession to fight injurious proposals. The representative body of the association has determined to postpone decision as to the attitude the profession should be recommended to take as regards consenting to work under the bill, until the proceedings in the committee of the House of Commons have been completed, and the bill as amended can be considered as a whole. In the meantime, the collective effect of the amendments already passed is being carefully examined and a report on the whole subject will be issued to the profession. Since the adjournment of parliament, the position has become acutely critical with respect to two of the most important principles for which the profession has been contending, namely, the free choice of physicians by patient and the freedom from friendly society control, and it is considered urgent that the profession should be put on its guard. The passing, by an overwhelming majority, of the amendment by which control of the administration of medical benefit was placed solely in the hands of local health committees, and the passing of the chancellor of the exchequer's amendment providing for free choice of doctor by patient, were received by the public as notable victories for the profession. But the British Medical Association warns the profession not to overvalue such success as has been gained since strenuous efforts are necessary to make the position secure. At conferences of friendly societies held after the conclusion of the committee proceedings in the House of Commons, resolutions hostile to the professional position have been carried and the desire has been manifested by the societies to retain control of what they call "their own doctors." Certain societies are endeavoring to rally to their support the physicians who hold appointments from them and to separate them from the general mass of their professional brethren. Attempts are being made to induce them to sign declarations in favor of the present system of appointment of medical officers by clubs, as against giving each member the choice of his own doctor. The British Medical Association has issued a circular to the whole profession asking physicians to appreciate the true bearings of the matter before signing to support the association by every possible means in preventing the perpetuation and extension, in connection with the national insurance bill, of the worst abuses of contract practice.

Hygienic Progress in Ireland

The Women's National Health Association of Ireland has done remarkable work in educating the people in the elements of hygiene and has played a great part in the antituberculosis movement in that country. It has taught the people to keep their windows open and has organized exhibitions and lectures all over the country. So ingenious have been some of its methods that they have been copied in England. The success of this movement is largely due to the indefatigable efforts of the president and the countess of Aberdeen, the Vicereine of Ireland. To mark their appreciation of her work the recent Congress of the Royal Institute of Public Health, held in Dublin, appointed her president—a position never before held by a woman.

PARIS LETTER

(From Our Regular Correspondent)

PARIS, Sept. 22, 1911.

Assistance to Physicians' Families

The Oeuvre Parisienne de Secours immédiat et d'assistance à la famille médicale (THE JOURNAL, Feb. 12, 1910, p. 548) has been organized to give aid to all of the members of any physician's family in misfortune. The membership fee has been reduced to one franc, and all the members of physicians' families are invited to cooperate. Non-medical persons who wish to show recognition to the medical profession are also invited to take part in the work, but the direction of the association is to be exclusively in the hands of physicians.

A Meeting for the Study of Abnormal Childhood

At the time of the twelfth Congrès français de médecine, which will be held at Lyons, October 22 to 25, a special independent meeting under its auspices will be held under the presidency of Dr. Beauvisage, professor in the Faculté de médecine de Lyon and president of the Oeuvre de l'Enfance anormale, to study the subject of abnormal childhood. All persons interested in the subject—professors, physicians, psychologists, instructors—may take part. No fee is demanded, the expense of the meeting being borne by the Congrès de médecine. The papers read will be published in medical, psychological and pedagogical journals as may seem most appropriate. Visits will be arranged to the psychopedagogical laboratories of the Oeuvre de l'Enfance anormale and to the medico-pedagogical laboratories of Villerubanne and Meyzieu.

Death of a Centenarian Physician

Dr. J. C. Boulle, whose centennial was celebrated March 3, 1910, has just died at Saint-Valérien in his one hundred and second year.

The High Cost of Living and the Public Charities

The municipality of Paris is greatly concerned over the increase in the cost of living, due to the epidemic of foot-and-mouth disease and to the unusual drought of the past summer. M. Felix Roussel, president of the municipal council, has just sent a letter to the presidents of the syndicats of the various food-supply industries expressing the desire to cooperate with them in lessening the expenses of living during the coming winter. The effect of this increase in the cost of foodstuffs is shown already in the budget of the Public Charities by a supplementary expenditure of about $190,000 (995,000 francs) for food. M. Mesureur, director of the Public Charities, has announced that when the municipal council meets again, he will be obliged to ask for additional funds with which to balance his budget.

Has a Physician the Right to Inject an Unauthorized Serum?

Under this title I described the prosecution of Dr. Lorot of Paris (THE JOURNAL, May 6, 1911, p. 1340) who injected his patients with a serum of his own make called "toxyline" which had not been legally recognized. This doctor was released in the first instance on the plea that the injections were a part of the treatment. The court of appeals of Paris confirmed the decision of the lower court, but the *cour de cassation*, to which the case was carried on appeal, has declared that a physician has no right whatever to make professional use of an unauthorized serum.

BERLIN LETTER

(From Our Regular Correspondent)

BERLIN, Sept. 21, 1911.

Personal

Professor Friedrich of Marburg has accepted the position of director of the surgical clinic at Königsberg.

Professor Veit of Halle has received the honorary title of doctor from St. Andrew's University, Glasgow, Scotland, on the occasion of the quincentenary of that institution.

A Medical Director for the Prussian Medical Bureau

It is a circumstance of unusual significance that the person who has hitherto occupied the office of director of the medical bureau having resigned on account of advanced age, Dr. Kirchner has been appointed in his stead. In this way the long-standing custom of appointing a lawyer as chief of the medical bureau, as of most departments, has been departed from and the wish of the Prussian medical profession, often expressed, to see a physician at the head of the medical bureau is fulfilled. This appointment was facilitated, or rather only made possible by the fact, which I have previously reported, that the medical bureau has been transferred from the department of education to that of the interior. In the department of education there was no inclination, on account of long custom and for other reasons, to make such a change.

Surely the prestige of the medical profession of Prussia will be enhanced by this appointment and there can be no doubt that our interests will be attended to with greater intelligence and cordiality by a man who has come from our own ranks than by a lawyer. Privy Councillor Kirchner is the oldest of the members of the bureau and for this reason was the only one considered in the appointment. But he has rendered good service in public health matters, particularly in framing the contagious diseases law. Kirchner is a pupil of Robert Koch and stood in intimate personal relations with him.

International Congress on Infant Protection

In the second week of September, the third international congress for protection of infants was held here. As the empress had assumed the protectorate and the imperial officials took a great interest in its organization (the president of the imperial health office was at the head of the committee on organization), it is easily understood that the affair came off in grand style. There were quite 1,000 participants present, among them men and women from all countries. The presidency as in all the international congresses of a philanthropic nature that have recently occurred in Berlin was filled by a prince, in this case the hereditary prince of Hohenlohe-Langenberg, formerly undersecretary in the imperial colonial office. The congress was opened September 11 in the presence of the empress. The proceedings were carried on in several sections which were under the direction of prominent investigators.

INFANT PEDIATRICS IN THE MEDICAL CURRICULUM

In the first section the chairman, Professor Heubner, delivered an address on the physiology and pathology of infancy in university instruction. He showed as the result of a question blank sent out that this branch is insufficiently provided for in the medical curriculum in most countries. He concluded with an appeal to the representatives of the various nations to direct a memorial to their governments, like the petition presented by the German pediatrists, asking for better facilities for instruction in this line. In the discussion of this theme Professor Marfan of Paris called for obligatory instruction to medical students in the hygiene and diseases of infancy in order to reduce infant mortality. Every children's clinic should have a special department for infants, with an infant consultation department for healthy and sick infants, which gives opportunity to receive the infants with the mothers. All students ought to attend this department for at least two months and pass a special examination in the care of infants. For the head of a crèche or a station for the care of infants, only such physicians should be selected as have had special experience and are able to show a certificate for the same.

Privat-docent Dr. Berend of Copenhagen expressed the desire that either the physiology and pathology of infancy be taught in a special elective, or that in the compulsory pediatrics course these subjects, as well as the hygiene of infants, should receive special attention. As the physiology and pathology of metabolism have special applications to the modern treatment of infants, it would be very appropriate to teach these subjects as an immediate continuation of the courses in physiology and pathology. Professor Koplik of New York called attention to the activity of American physicians during the last twenty-five years in furthering infant hygiene. He expressed a wish for a separation of the study of infancy from that of later childhood, the play and the school age, and the establishment of separate chairs for the hygiene of the child and for the study of children's diseases. Professor Medin of Stockholm gave a historical review of instruction in pediatrics in Sweden, where already in 1845 a professorship for pediatrics was established, and in 1850 a special children's clinic was founded in Stockholm. The number of students taking the compulsory course in the pediatric clinic ought not to exceed twenty-five, in order to promote practical training as much as possible.

TRAINING IN THE CARE OF INFANTS

The education of the nursing force for institutions, families and communities brought out a greater discussion. Professor Feer of Zurich required for women who are willing to devote themselves to the profession of infant nursing, in addition to good physical health, a specially good education and intelligence, which must be in many respects greater than that required for other nurses, as the infant cannot express its sensations. The duration of instruction should be at least one year in a sanatorium or hospital for infants, and the subjects for instruction should be anatomy, physiology, nutrition, hygiene and social care, and they should be taught partly theoretically and partly practically at the bedside of the healthy and the sick infant by a physician and by the head nurse. It is desirable that a four to six weeks' course should be given in a lying-in hospital in order that the nurse may also be able to care for the mothers. Pupils younger than twenty years should not be received, as they are not capable of the efforts of the instruction period. After a successful period of instruction the pupil should receive the title of graduate trained infant nurse (*diplomierte Säuglingspflegerin.*)

The well-known pediatrician, Privy Councillor Taube (who has established model infant hygiene in Leipsic), reported on communal infant hygiene. He called attention to the importance of a municipal control of the construction and character of dwellings, as, especially in the smaller dwellings, the condition of infants is endangered by the overheating as a result of insufficient ventilation. Female officials experienced in the care of infants should be installed as inspectors of dwellings. Municipal lying-in homes for the reception of needy women and girls should be erected and breast-feeding should be encouraged by municipal arrangements (nursing premiums, stations for the care of infants and nursing rooms). A better training in the care of infants should be required of the midwives licensed by the municipality. Of especial importance is a law for providing a cheap milk that is unobjectionable on the ground of health. Illegitimate children need special oversight through the establishment of municipal general guardianship. The speaker described in detail the conditions in Leipsic, where a municipal pediatrician stood at the head of the entire public infant welfare system. Nathan Straus of New York, an official delegate from the United States, spoke of the progress which had been made in the care of infants in America, in connection with which he went extensively into the favorable effect of pasteurized milk, for the introduction of which he himself, as is well known, has spent millions.

MOTHERHOOD INSURANCE

Dr. Bruno, the president of the propaganda society for insurance of motherhood in Heidelberg, gave an address on this important subject. He held that the heavy expenses of motherhood insurance necessitated its support by the state more than any other branch of insurance. There can be no protection of infants without a sufficient care for the mother, as in Germany in a year 1,500,000 women were found to be without sufficient protection before, during and after birth. These efforts for the protection of motherhood should be directed toward an imperial legal regulation, similar to the legal conditions already provided, for the protection of lying-in women in the wage-earning classes and for an amplification for the same. As indispensable requirements for state-aided obligatory insurance, the following are important: compensation for wages, to the extent of a full day's wage, for ten weeks, four weeks before and six weeks after delivery; compensation for the cost of the midwife, physician, medicines and for necessary care at home or in the hospital, and nursing premiums or assistance in the nutrition of the infant. Inasmuch as this imperial regulation of the matter is not probable in the immediate future, the method of self-help and of private insurance must be adopted. This can be made possible by propaganda societies for motherhood insurance, which collect the means for founding motherhood clubs of which the chief function is the encouragement of breast feeding. Private motherhood societies make it possible for all women without reference to trade, religion or social status, whose income is under $760 (3,000 marks) to secure proper assistance at the time of confinement by the payment of small sums, and thus to preserve the health of the mother and child. The propaganda society provides suitable care in the last four weeks of pregnancy, and in return for a small payment provides in case of need for the care of the house and for the delivery of the insured. The private motherhood insurance aims at purely economic and hygienic ends, and refrains from one-sided ethical, political or sectarian activity.

STATISTICS

Dr. Falkenburg in the section for statistics made an address on the morbidity, mortality and birth-rate in different countries, illustrated by numerous graphic representations. While the birth-rate has fallen very markedly in all European countries with the exception of Roumania, Bulgaria and Russia, the reduction in the general mortality is notably greater in all countries with the exception of Ireland and France, but the infant mortality remains relatively high. The German nation has taken an unfavorable position among the European states. So far as sufficient statistics on morbidity are available, it must be said that disturbances of digestion are the chief cause of the diseases and mortality of infants. In the discussion, Professor von Mayr of Munich asserted that the theory of the survival of the fittest (*Auslesetheorie*) with reference to infant mortality must be looked on as obsolete. The connection between the birth-rate and mortality is to be assumed, as indicated by the fact that the mortality rate increases with the birth-rate. This connection was also emphasized by Szana of Budapest. Even the very active efforts for hygiene have not been able to do away with this parallelism. Kuczynski of Schöneberg asserted that it was extremely difficult to demonstrate such a parallelism, as well as to refute it.

OTHER TOPICS DISCUSSED

I cannot enter into the consideration of the other addresses. On the third day of the congress a consideration of existing arrangements for the care and protection of infants occurred in the various groups. At the final session the general secretary, Professor Keller, laid before the congress the suggestions made in the various sections; thus the assistance of states and societies in instruction of wider circles of the population in the protection and care of infants was advocated; further, the representatives of various countries were requested to urge their governments to provide new institutions for instruction in the university. It was further advocated to collect uniform international statistics on the entire subject of infancy. The necessity of the development of international relations of guardianship and legal protection in the care of infants in general (more protection than previously for illegitimate children, etc.) was strongly emphasized. In connection with this, the establishment of an international information bureau for all legal questions in regard to the protection of children was proposed. The next congress will occur four years hence at The Hague in Holland. Eight years hence it will presumably meet at London.

Marriages

James D. Dodrill, M.D., Webster Springs, W. Va., to Miss Mabel I. Harford of Richwood, W. Va., at Charleston, W. Va., September 26.

Lee J. Ernstberger, M.D., Oklahoma City, Okla., to Miss Lasetta S. Smodell of Louisville, Ky., at Vincennes, Ind., August 9.

John H. Steenbergen, M.D., Huntingdon, W. Va., to Miss Jessie Johnson Fitch at Fairmont, W. Va., September 20.

James William Huffman, M.D., Poland, Ind., to Miss Stella Kinland of Bismarck, Mo., at St. Louis, September 30.

Claude Jackson Martin, M.D., Clarksburg, W. Va., to Miss Edith Claire Riall of Baltimore, September 13.

Edwin W. Patterson, M.R.C., U. S. Army, to Miss Mary Laura Kriedler of Georgetown, D. C., September 6.

William Henry Best, M.D., Brooklyn, N. Y., to Miss Mary Anderson Kinsley of Philadelphia, September 29.

Edward Jonathan Klopp, M.D., Philadelphia, to Miss Emma Rille of Johnstown, Pa., September 27.

John Ross Beiter, M.D., to Miss Euretta Pamelia Kingsbury, both of Norwalk, O., September 30.

Edwin Janss, M.D., Los Angeles, Cal., to Miss Florence Cluff of San Francisco, September 12.

Henry James Reynolds, M.D., Chicago, to Mrs. Caroline W. Reid of Ottawa, Ill., October 4.

John Arthur Turner, M.D., Waukegan, Ill., to Miss Hazel Irene Kline of Chicago, October 5.

Deaths

Henry Gibbons, Jr., M.D., for many years dean of Cooper Medical College, San Francisco; died at his home, September 27, from senile debility, aged 71. He was born in Wilmington, Del., the son of Dr. Henry Gibbons, and was graduated from the Medical Department of the University of the Pacific, San Francisco, in 1863; for two years thereafter he served as acting assistant surgeon, U. S. Army at the General Hospital, Washington; he returned to San Francisco in 1870, became dean and professor of materia medica in Cooper Medical College; and in 1882 was made professor of obstetrics, gynecology and diseases of children; from 1870 to 1873 he was health officer of San Francisco; a member of the board of health from 1880 to 1883, and of the board of education from 1889 to 1890; he was a member of the American Medical Association; a charter member and once president of the Medical Society of the state of California, and the San Francisco Medical Society. Dr. Gibbons was one of the most prominent and progressive men on the Pacific Coast, and a practitioner and administrative officer of marked ability.

Robert Edward Doran, M.D. Albany (N. Y.) Medical College, 1893; a member of the American Medical Association and American Medico-Psychological Association; assistant physician at the Craig Colony for Epileptics, Sonyea, N. Y. from 1901 to 1903; first assistant physician in the Willard State Hospital from 1895 to 1901, and later superintendent of that institution; appointed state medical inspector for the lunacy commission in May, 1910; and a year later appointed superintendent of the Long Island State Hospital; an alienist of great merit and an administrative officer of ability, efficiency and energy; died at his home in Brooklyn, September 23, from heart disease complicated by laryngitis, aged 40.

Arthur L. Osborn, M.D. Western Reserve University, Cleveland, 1873; a member of the Ohio State Medical Association and National Association of Railway Surgeons, and once president of the Huron County Medical Society; a veteran of the Civil War; for twenty years major-surgeon of the Sixteenth Infantry N. G. Ohio, and surgeon of the Sixth N. G. Ohio during the Spanish-American War; a member of the board of U. S. pension examining surgeons of Norwalk; local surgeon for the New York Central Lines and Wheeling and Lake Erie Railroad; died at his home in Norwalk, September 18, aged 64.

Zane Bland Taylor, M.D. Medico-Chirurgical College of Philadelphia, 1893; a member of the Medical Society of the State of Pennsylvania; formerly physician to the Huntingdon County Home, Shirleysburg; for many years a member, and at the time of his death president, of the school board of Orbisonia; formerly a member of the council and burgess; died at his home, September 18, aged 61.

Merton Oliver Edwards, M.D. Medical School of Brunswick, 1881; a member of the Maine Medical Association; from 1906 to 1908 a member of the state legislature and in 1910 state senator; postmaster of Monmouth for four years; for many years a member of the staff of St. Mary's General Hospital; died at his home in Lewiston, September 22, from nephritis, aged 59.

George R. Vernon, M.D. University of Pennsylvania, Philadelphia, 1875; for several years a lecturer at his alma mater; president of the Upper Darby (Pa.) Board of Health, and formerly president of the Clifton Heights Board of Health and a member of the school board; died at his home in Clifton Heights, September 16, from cerebral hemorrhage, aged 64.

Charles Edward Denhard, M.D. New York University, New York City, 1874; a member of the Medical Society of the State of New York and New York Academy of Medicine; a member of the staff of Bellevue, Charity and Park hospitals, and one of the founders of the German Poliklinik; died at his home in New York City, September 22, aged 71.

John Archibald Wilder, M.D. Albany (N. Y.) Medical College, 1895; of Denver; a member of the Colorado State Medical Society, American Climatological Association and National Association for the Study and Prevention of Tuberculosis; professor of pathology of the University of Denver, and pathologist to St. Luke's and St. Joseph's hospitals; for two years assistant at the Saranac Lake Sanatorium; died at the home of his mother at Hoosick Falls, N. Y., September 14, from pulmonary tuberculosis, from which he had suffered for fifteen years, aged 40.

Walter H. Peters, M.D. Medical College of Ohio, Cincinnati, 1886; a member of the American Medical Association, and for twenty years a specialist on diseases of the eye, ear, nose and throat, of Lafayette, Ind.; an expert analytical chemist and toxicologist; a member of the staff of St. Elizabeth's Hospital; died at his home in Lafayette, September 28, from cancer, aged 52.

George Titus Howland, M.D. Bellevue Hospital Medical College, 1886; formerly health officer of Washington, D. C., and a leader in the crusade for the improvement of sanitary conditions in dairies; for the last nine years a practitioner of Norwich, Conn.; died in a hospital in Boston, September 24, a day after an operation for appendicitis, aged 50.

Alva Leroy Paul, M.D. Long Island College Hospital, Brooklyn, 1875; of Ottawa, O.; a member of the Ohio State Medical Association; local surgeon for the Detroit, Toledo and Ironton Railroad, and a member of the local board of pension examining surgeons; died at a hospital in Cleveland, September 18, from heart disease, aged 63.

Samuel S. Kilvington, M.D. University of Buffalo, N. Y., 1883; a member of the Minnesota State Medical Association; formerly health commissioner of Minneapolis; a veteran of the Riel Rebellion; died at his home in Minnetoka Mills, Minn., September 25, from cerebral hemorrhage, aged 69.

James Alfred Pettit, M.D. University of Virginia, Charlottesville, 1896; of Roseland, Va.; a member of the governor's staff; was shot and instantly killed in front of a hotel in Lovingston, Va., September 25, aged 45. The cause of the shooting is said to have been an ancient grudge.

Joseph Westerfield Dodds, M.D. Miami Medical College, Cincinnati, 1888; a member of the Ohio State Medical Association, and for many years a district physician of Cincinnati; died at the home of his father-in-law in Hamilton, O., September 25, from nephritis, aged 51.

John J. Cannan, M.D. College of Physicians and Surgeons, Baltimore, 1892; a member of the Medical Society of the State of Pennsylvania, attending physician to the Bradford Hospital; died at his home in that city, September 23, from pneumonia, aged 43.

Uriah Davis Thomas, M.D. Botanico-Medical College of Ohio, Cincinnati, 1875; a charter member of the Minneapolis Writers' League and a poet of more than local reputation; died at his home in Minneapolis, September 16, from senile debility, aged 83.

Absalom Winfield Jones, M.D. University of Michigan, Ann Arbor, Mich., 1878; a member of the American Medical Association, and Columbus Academy of Medicine; died suddenly at his home in Westerville, O., September 21, from heart disease, aged 64.

Isaac M. Witmer, M.D. Jefferson Medical College, 1881; a member of the Lancaster County (Pa.) Medical Society, and coroner of the county for nearly thirteen years; died at his home in Lancaster, September 22, from cerebral hemorrhage, aged 60.

Lewis Eugene Beauharnais Sanborn, M.D. College of Physicians and Surgeons, New York City, 1867; a veteran of the Civil War; deputy health officer of New York City from 1879 to 1908; died at his home in Machiasburg, Me., September 24, aged 73.

Almon Ward Hill, M.D. Boston University School of Medicine, 1887; of Concord, N. H.; a member of the New Hampshire legislature in 1903 and 1905; died in the Homeopathic Hospital, Boston, September 17, after a surgical operation, aged 47.

John J. Harlan, M.D. University of Alabama, Mobile, 1872; probate judge of Tallapoosa County, Ala., from 1898 to 1904, and later a banker of Stamford, Tex.; died at the home of his son in Alexander City, Ala., August 26, aged 64.

James M. Davis, M.D. University of Louisville, Ky., 1871; secretary of the board of health of Greenville, Ind., and a member of the Floyd County Medical Association; died at his home, June 14, from cerebral hemorrhage, aged 78.

Alfred E. Sherwood, M.D. University of Pennsylvania, Pa., 1873; of Union City, Pa.; local surgeon to the Pennsylvania System; and member of the board of health; consulting physician to the Corry Hospital; died at his home, September 24, aged 62.

Napoleon B. Nevitt, M.D. University of Maryland, Baltimore, 1857; a member of the Medical Society of Virginia; surgeon in the Confederate service during the Civil War; died at his home in Accotink, September 25, aged 81.

David H. Davis, M.D. University of Vermont, Burlington, 1891; a member of the Medical Society of the State of New York; health officer of East Worcester; died at the home of his daughter in Schenevus, September 23, aged 54.

Luther M. Zimmerman, M.D. University of Maryland, Baltimore, 1864; surgeon in the Federal service during the Civil War; for several years postmaster of Myersville, Md.; died at his home in Hagerstown, September 13, aged 71.

Frederick G. Trowbridge, M.D. University of Buffalo, N. Y., 1883; a member of the Jefferson County (N. Y.) Medical Society; died at his home in Watertown, September 20, from cerebral hemorrhage, aged 53.

William T. Eikner, M.D. Milwaukee Medical College, 1901; proprietor of a hospital and sanitarium in Mason City, Nev.; was shot and killed in an altercation in a hotel in Mason City, September 19.

J. B. Humphrey (license, West Virginia, 1881); for many years a practitioner of Harrison County; died at the home of his daughter in Wilsonburg, September 7, from senile debility, aged 80.

Ada Benton Morgan, M.D. Hahnemann Medical College of Chicago, 1894; died at her home in Ridge, a suburb of Chicago, September 23, three days after an operation for appendicitis, aged 52.

William Acrill Fort (license, South Carolina, years of practice), a Confederate veteran and a practitioner since 1870; died at his home in Gaffney, September 21, from heart disease, aged 69.

Joseph G. Hodgkinson, M.D. St. Paul (Minn.) Medical College, 1886; of South St. Paul; died at Luther Hospital, St. Paul, September 16, from arteriosclerosis, aged 66.

Nelson W. Shugert, M.D. College of Physicians and Surgeons, Baltimore, 1885; died at his home in Tidioute, Pa., September 12, from heart disease, aged 51.

Alexander M. Smoot, M.D. University of Tennessee, Nashville, 1889; died at his home in Knoxville, Tenn., August 30, from nephritis, aged 59.

Louis W. Heydrich, M.D. Western Reserve University, Cleveland, 1885; of Toledo; died in Erlangen, Germany, September 15, aged 51.

Austin Shuey, M.D. Eclectic Medical Institute, Cincinnati, 1890; died at his home in Prospect, O., June 30, from acute gastritis, aged 51.

F. A. Brickley, M.D. St. Louis College of Physicians and Surgeons, 1886; died at his home in De Soto, Mo., September 14, aged 80.

John F. James, M.D. Lincoln (Neb.) Medical College, of York, Neb.; died at a hospital in Lincoln, September 20, aged 40.

Edward D. Crispell, M.D. Eclectic Medical Institute, Cincinnati, 1866; died at his home in Leadville, Colo., September 12.

Charles C. Cage, M.D. Tulane University of Louisiana, New Orleans, 1861; died at his home in Monroe, La., aged 86.

Minot G. Jenison, M.D. Howard University, Washington, D. C., 1882; died recently at his home in Hollywood, Cal.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession.

THE PHYSIOLOGIC STANDARDIZATION OF ERGOT

Reference was made editorially in The Journal October 7 to a study of the question of the physiologic standardization of ergot by Edmunds and Hale, in which they review the various methods employed in the standardization of the drug and give the results of their own work with proprietary and pharmacopeial preparations of various manufacturers.

Their report is a highly interesting document and it is presented here in order that physicians may know how much reliance is to be placed in the preparations of manufacturers and what serious discrepancies exist between the claims made for permanency, strength, etc., of their special products and the facts as brought out by experiment. A summary of their conclusions as to the method of standardization is also given.

"From the standpoint of both practicing physician and patient an interesting part of this research relates to the activity of various ergot preparations as they are obtained on the open market. Similar work has been reported on by various writers from time to time, but even their results show some interesting discrepancies which seem to be dependent partially at least on the special method of assay employed. The examination of these specimens by us was not the prime object of the work, but only an incidental part, as it was mainly concerned with an examination of the different methods of assay in general use.

"Dixon, using the blood-pressure method, reported that among six samples of ergot he found two moderately active, two very feeble, and two worthless. Edmunds and Roth, by means of the cat's uterus, found that in a series of fluid extracts six were of nearly the same activity, one about half strength and one apparently inactive. Kehrer reports on about twenty-five ergot preparations which he assayed in the course of his investigations on the isolated uterus. Goodall, in his work already referred to, reports on the examination of a large number of ergot preparations. Among these he found that almost 60 per cent. showed themselves to be very poor when judged by the blood-pressure standard, but that only 34 per cent. failed to cause satisfactory contractions of the uterus. Wood and Hofer seem to have had the most discouraging experiences with fluid extracts, as they found among eleven preparations only two which came up to their standard of activity as determined by the effect on the blood-pressure.

"Our own results obtained in this research showed that the six fluid extracts which were obtained in the open market possessed considerable variation in activity, some being four times as strong as others, as is seen in the following table. Only one of the entire number approached in strength the fluid extracts made from the Spanish and Russian ergot.

"Relative activity of preparations of ergot examined. Results of July and December assays.

Spanish ergot	5*
Cornutol (H. K. Mulford Co.)	5
Russian ergot	6
Nelson, Baker & Co., fluid extract	6
Ergone (Parke, Davis & Co.) Sample 2	8
Wyeth purified ergot	8
Parke, Davis & Co., sample 2, fluid extract	9
Sharpe & Dohme, fluid extract	10
Ray Chemical Co., fluid extract	11
Ergotole (Sharpe & Dohme)	15
Parke, Davis & Co., sample 1, fluid extract	20
H. K. Mulford, fluid extract	20
Ergone (Parke, Davis & Co.), sample 1	?

"As it is so generally known that the fluid extracts of ergot deteriorate quite rapidly, the fact that some preparations on the market which are made according to the pharmacopeia may be found very weak need not be considered a reflection on the manufacturer, as it may be merely the result of aging or other causes. It would seem very desirable, however, on account of this deterioration with age that bottles of ergot should be stamped with the date of the manufacture.

"With preparations of ergot other than those made according to pharmacopeial directions, the condition is quite different. These are prepared according to some private formula and are represented as being superior to the official preparations, either on account of greater strength, permanence, or some other suggested superiority. With these it is therefore of importance to see whether they possess any advantage over the cheaper official preparations and whether they actually conform to the standard claimed.

PREPARATIONS EXAMINED

"Cornutol appears at the head of these non-pharmacopeial preparations, and our sample seemed to be equal in activity to the Spanish ergot fluid extract. This preparation is made by H. K. Mulford Co., Philadelphia, from 'selected Spanish ergot and contains what is active separated from inert matter,' and is said to be assayed so as to contain 0.15 gram cornutin in 100 c.c. The specimen we examined was a thick greenish-brown fluid with a very unpleasant odor which suggested putrefaction. The most interesting point in connection with our sample of cornutol was that while it was found to be equally active with a good fluid extract, it should have been much more potent as it is claimed to be two and a half times as strong, each minim according to the label being equal to 2½ grains of ergot. We must conclude, therefore, that it, like the official preparations, had undergone deterioration.

"The 'ergot purified' made by John Wyeth & Bro., Philadelphia, made up with 25 per cent. alcohol, was a clear Burgundy red, and possessed the characteristic ergot odor. It required a dose about 50 per cent. larger than a good fluid extract in order to produce equal effects, and yet according to the makers it is a 'concentrated purified solution of active constituents of ergot, physiologically tested and standardized.' The method of assaying is not stated, but if we can judge by the copy of tracing enclosed, the preparation is tested by the blood-pressure method. Here again, as with cornutol, the only explanation we have to offer as to the difference in strength between that indicated on the label and what we found on examination is that it must have deteriorated very considerably.

"Still more interesting is 'ergotole,' made by Sharpe & Dohme, Baltimore. One specimen was found to be about one-third as strong as our Spanish fluid extract, while according to the makers it should be two and one-half times stronger, as each cubic centimeter is said to be equal to 2.5 grams select Spanish ergot. Our first thought would be that this remarkable discrepancy could be explained as in the other cases by the effect of age on the preparation, but this is evidently a mistake, as the firm's literature positively states that ergotole is a 'permanent solution,' that 'it does not change with age,' and is 'therefore always reliable.' Confronted by these statements, we are entirely at a loss for an explanation and must leave the subject with the mere statement of facts. Further, this preparation is assayed by the cornutine of Keller which the makers have found to be a 'trustworthy guide as to the therapeutic strength of the drug.' The evidence in regard to this relation we discussed at another point. A statement which occurs in the literature of the firm is that ergotole contains all the active principles of ergot in an 'unchanged condition' and 'in their natural combination.' The question might be raised as to whether this is not rather a strong statement and one which would be hard to prove.

"'Ergone,' Parke, Davis & Co., appears in both our series of assays, as the results obtained with it in July were so unfavorable that we decided to examine it again in December. According to the manufacturers, it is of the same strength as the official fluid extract, is non-alcoholic, sterile, active, permanent, and physiologically tested and standardized. The December samples we examined compared very favorably with the fluid extract made by the same firm whether the comparison was made on the cock's comb or the uterus. It apparently was slightly stronger, but not over about 10 per cent. However, both were much weaker than the Spanish fluid extract, being not much more than half as active. If the fluid extract had deteriorated (as might be expected), it would look as if ergone must have deteriorated also, as they are both standardized. But how can ergone deteriorate, being a permanent solution? Either they were both weak to start on, or they have deteriorated. The latter view probably is correct if we may judge by the findings in the samples used in the July series of assays. This specimen when tested on the cock's comb produced no cyanosis whatever, even when it was given in 4 c.c. and 6 c.c. doses. An extract from our records on one cock will show very plainly its lack of activity.

---

* The numbers represent the amounts of the various ergot preparations that were required to produce a given degree of cyanosis in a cock's comb. For example: While five parts of Spanish ergot produced the required degree of cyanosis, it took ten parts of Sharpe & Dohme's fluid extract and twenty parts of Parke, Davis & Co.'s fluid extract to produce the same effect.—Ed.

"Cock: Weight, 1,285 grams. Aug. 26, 1910. Injected 1 c.c. Spanish fluid extract. Distinct cyanosis. Same intensity as 3 c.c. ergotole injected to-day. Aug. 29, 1910. Injected 6 c.c. ergone. No action. Aug. 31, 1910. Injected 1.5 c.c. Spanish fluid extract. Distinct cyanosis.

"This protocol shows the cock was reacting well to other preparations, so that the failure to react must have been due to the ergone. This same specimen of ergone when administered in 1 c.c. doses to a cat called forth uterine contractions which were not as strong as were being produced by 0.1 c.c. doses of Spanish fluid extract. Clearly then the ergone was nearly inactive and must have deteriorated greatly.

"An interesting point in connection with the assay of ergone is the effect it produced on the blood-pressure. By reference to the tables [for which the *Bulletin* must be consulted.—Ed.] it will be seen that in both series it is very weak when measured by this standard. This is especially noticeable in the sample used in December, which was quite active when tested *on the cock's comb and uterus, yet it raised the blood-pressure* only 9 per cent., in comparison with the 38 per cent. increase produced by Parke, Davis & Co.'s fluid extract. This lack of activity on the blood-pressure is probably explained by a relatively small quantity of putrefactive amines, as ergone is said to be made under aseptic conditions.

"Chemical methods for the assay of ergot show little relation to biologic methods, and the latter should be used as a means of insuring those who require this drug a remedy both potent and of uniform strength.

"For this purpose, the method using the cock's comb is recommended on practical grounds rather than that using the uterus.

"Ergot preparations should be marked with the date of manufacture.

"The fluid extracts of ergot examined varied in strength greatly, some being only about one-fourth as strong as a preparation freshly made from Spanish ergot. Non-pharmacopeial preparations showed even greater discrepancies between the strengths claimed and those actually found.

"Until more reliable methods of manufacture are found makers of ergot preparations would be wise to exclude the phrase, 'ergot in permanent solution,' from their advertising literature. They may thus avoid misbranding."

QUININ TANNATE

Report of the Council on Pharmacy and Chemistry

The following report was adopted by the Council and its publication authorized. In accordance with the recommendation, the description of quinin tannate, appearing in New and Nonofficial Remedies department of this issue, requires a quinin content of not less than 29 per cent. and lists, as brands which comply with this standard, the products sold by the Mallinckrodt Chemical Works, the New York Quinin and Chemical Works and the Powers-Weightman-Rosengarten Company.

W. A. Puckner, Secretary.

Quinin tannate, being almost insoluble in water, is practically tasteless and therefore adapted for administration to children in the form of mixtures (suspensions). Although the absorption of this quinin salt is claimed to be somewhat uncertain and its tannin content is an objection, the Council decided to describe it in New and Nonofficial Remedies because of its general availability and its rather general recognition. But in view of the common unreliability of little used substances, the actual description of quinin tannate in New and Nonofficial Remedies was postponed until the market supply could be examined and standards for the preparation formulated.

An exhaustive and critical search of the literature, as well as a chemical investigation of this substance, has been made in the Association's chemical laboratory. The results of this investigation were reported by W. A. Puckner and L. E. Warren in a paper read before the Scientific Section of the American Pharmaceutical Association, and to be published in the Annual Reports of the Chemical Laboratory. In brief the findings are:

Quinin tannate is official in most foreign pharmacopeias, but not in that of the United States. In some of them methods for preparation are given and the official product in all cases is required to contain not less than 30 per cent. of anhydrous quinin alkaloid. The methods prescribed by these pharmacopeias, however, were found in the Association's laboratory to yield products which did not contain the stated amount of alkaloid. As a result of considerable experimentation and consultation with the manufacturers of quinin tannate in this country, a simple method of making the substance was worked out, which will enable anyone at all familiar with pharmaceutical operations to make a preparation of good quality.

Four commercial brands of quinin tannate were examined with the results shown in the accompanying table. From these findings it appears that the quinin tannate of the New York Quinin and Chemical Works is of good quality and contains more than 30 per cent. quinin. The products of the Brunswick Chemical Works (Mallinckrodt Chemical Works, selling agents) and the Powers-Weightman-Rosengarten Co. are satisfactory except that their quinin content is somewhat low. The Merck brand contains about 9 per cent. of free quinin, is bitter and is, therefore, not fit for use. The poor quality of this brand is a further illustration of the need of controlling the quality of medicines, particularly when these are not of much commercial importance.

Inasmuch as the authors have shown that quinin tannate with more than 30 per cent. quinin can readily be made, a preparation with less alkaloid should not be permitted. However, as two brands approach this standard and, as the interested firms will not find it difficult to meet the proposed standard, the referee recommends a temporary standard of not less than 29 per cent. quinin, which standard is to be increased so as to require a quinin content of not less than 30 per cent. by Jan. 1, 1913. It is recommended that the description of quinin tannate submitted be accepted for inclusion with New and Nonofficial Remedies and that the product of the New York Quinin and Chemical Works, of the Brunswick Chemical Works (Mallinckrodt Chemical Works, selling agents), and of the Powers-Weightman-Rosengarten Co. be listed as brands which meet the requirements of this description. It is further recommended that, beginning with 1913, a quinin content of from 30 per cent. to 35 per cent. be required.

In order that physicians may know the facts in the case, it is recommended that publication of this report be authorized.

Number or Brand.	Water (Loss at 100°).	Anhydrous Quinin.	Ether-Soluble Matter.†	Sulphate.	Chlorid	Taste of Filtrate.
P. W. R.	7.88	29.30	0.10	Distinct turbidity	Noticeable opalescence	Noticeably bitter.
Brunswick (M. C. W.).	6.50	29.51	0.19	Absent	Very marked opalescence ...	Noticeably bitter.
N. Y. Q.	8.05	33.36	0.36	Distinct turbidity	Noticeable opalescence	Noticeably bitter.
Merck	9.06	33.97	9.02	Very faint opalescence	Very faint opalescence	Very bitter.

† In general, the values given in this column should indicate the presence of uncombined alkaloid, but quinin tannate is slightly soluble in anhydrous ether; hence the test must be carried out under arbitrary conditions and the residue obtained tested for uncombined alkaloid. The three specimens in which the ether-soluble matter amounted to less than 0.4 *per cent.* contained no uncombined alkaloid.

EDITORIAL COMMENT

In order that pharmacists might be in a position to dispense a good quality of quinin tannate, the examination of the Association's chemical laboratory above referred to was presented to the American Pharmaceutical Association at its recent annual meeting in Boston. While the very simple directions for its preparation which were worked out should make it possible for every pharmacist to prepare his supply of this drug, it was feared that the pharmacist would continue to place his faith in the drug as found on the market and hence the quality of the several available brands was also given in the report. This would have enabled the pharmacist to give preference to those brands which were shown by examination to be of a satisfactory grade. Unfortunately for the pharmacist, as well as for the physician and his patients, those interests which are not in sympathy with the Association's policy of giving publicity to the makers of worthless or adulterated drugs, appear to have been in control when the paper was read and were able to carry a motion that the names of manufacturers be omitted from the paper when it should appear in the American Pharmaceutical Association's publication. In view of this, physicians who use quinin tannate should, in their prescriptions, take the precaution to specify a brand of the drug which was shown to be reliable or, perhaps better still, indicate that they want a brand which corresponds with the standards established by the Council, by appending the letters N. N. R., thus "Quininæ tannas, N. N. R."

Correspondence

Treatment of Rhus Poisoning

To the Editor:—I read with interest the communication of Dr. Robert T. Morris of New York on the treatment of rhus poisoning (The Journal, Sept. 30, 1911, p. 1152). There is no statement as to the date of discovery by Dr. Berryhill, U. S. N., of the soap-suds treatment, but the method is familiar to many clinicians in the Boston hospitals, and I myself have used and recommended the same remedy since 1902. I have never before seen any reference to it in the literature, but I admit that I never looked for it.

C. S. Oakman, Detroit.

To the Editor:—In his 1911 edition Pusey quotes, from The Journal, March 17, 1906, Balch's treatment of ivy poisoning, which is substantially the same as that ascribed to Dr. Berryhill by Dr. Morris in The Journal, September 30. I have tried the treatment with soap-suds scrubbing and alcohol and find it very effective, giving immediate relief.

J. L. Buttner, New Haven, Conn.

To the Editor:—In the *Journal of Biological Chemistry*, 1907, ii, No. 6, S. F. Acree and W. A. Syme relate the results of an exhaustive study of rhus poisoning in a paper entitled "The Composition of Toxicodendrol." They found that the poisonous principle was neutralized by permanganate of potash, used preferably in warm 2 to 4 per cent. watery solution.

For nearly twenty years I was regularly a sufferer from ivy poisoning; and on two occasions the condition was alarming. None of the usual remedies had any effect, except to modify the extreme distress. Permanganate this year and last gave almost instant relief, checking the disorder even when started on the face.

From experience and observation I have formulated the following treatment: No scratching. No ointments in the acute stage. No bandages, for these tend to spread the poison to the surrounding skin. If any protector is needed, let it be a loosely applied dressing of cotton and gauze, kept moist at all times with a mild alkaline solution, and changed at frequent intervals. Frequent and copious washings with lukewarm water and an unirritating soap. Occasionally, after the parts are washed, a 2 per cent. watery solution of permanganate of potash. If treatment has been begun late, and a condition of eczema exists after the activity of the poison has ceased, then soothing ointment may be permitted.

Permanganate of potash stains the skin a deep brown color, but this is a small price to pay for the relief it affords. A 5 per cent. solution of oxalic acid will remove the discoloration, but caution must be exercised in applying it. Alcohol is a solvent of the poisonous principle, but its use tends to spread the trouble. In handling the inflamed surface, it is best to use rubber gloves.

Addison W. Baird, New York.

To the Editor:—Please revise Dr. Hemmeter's formula for bismuth subgallate ointment given in his communication on the treatment of rhus poisoning. To a careful reader the transposition of quantities is evident, but many will use the formula as printed.

William Crawford Johnson, Frederick, Md.

Comment.—The subject of ivy poisoning is commented on editorially in this issue. In regard to Dr. Hemmeter's formula, Dr. Johnson is correct. We therefore repeat the formula with corrected quantities:

Bismuth subgallate	ʒi
Solution epinephrin (adrenalin chlorid) 1-1000...	100 ♏
Lanolin	ʒv
White petrolatum q. s.......................ad	℥i

The Introduction of the Ophthalmoscope into the United States

To the Editor:—I wish to correct the statement with reference to the introduction of the ophthalmoscope into this country, made by Dr. A. D. Williams, of Bedford, Ind., in The Journal, July 29, 1911, p. 408. The credit is due neither to Dr. E. Williams, of Cincinnati, in 1855, nor to Dr. Herman Knapp, of New York, in 1868, but to Dr. Christopher Johnston, who on his return from a prolonged stay in Europe, early in 1854, brought the instrument back with him to this city. In a report made by him to the Medical and Chirurgical Faculty of Maryland, on June 7, 1854 (Transactions for 1854), he exhibited and described it. He had made himself thoroughly familiar with it by studies in Berlin, with von Graefe, and in Paris with Desmarres. Dr. Johnston's report is accompanied by two ophthalmoscopic drawings and it is "highly probable that the very first colored drawings of the background of the eye, published in America, were those which he prepared" (Theobald, Samuel: "The Evolution of the Ophthalmoscope and What It Has Done for Medicine," *New York Med. Jour.*, June 22, 1901). The only article on the ophthalmoscope published in this country prior to Dr. Johnston's report, so far as I am aware, is a translation, somewhat condensed, of Helmholtz's original tract, by Dr. W. R. Sanders, which appeared in the *American Journal of the Medical Science*, July, 1853, and was copied from the English *Monthly Journal of Medical Science*, July, 1852.

Dr. Johnston was a highly accomplished scientist as well as physician, and held in the University of Maryland successively the chair of anatomy (1864-66) and that of surgery (1869-81).

Eugene F. Cordell, M.D., Baltimore,
Professor of History of Medicine, University of Maryland.

Anesthetic Records

To the Editor:—For a number of years I have been collecting anesthetic records with the object in view of being able some day to present to the profession what might possibly be accepted as a standard chart—at least as to contents. With this in view I have written to many hospitals for copies of the charts they use, and have been gratified at the number of responses which were received. In order now to reach my colleagues who have their own private blanks, I must have recourse to this general request. I would ask those who are interested in this subject kindly to send me four copies, one for the Long Island Society of Anesthetists, one each for the King's County and the New York Medical libraries, and one for my own collection. I shall be glad to correspond with any one on this matter and to send our chart (the Long Island College Hospital) in return.

A. F. Erdmann, Brooklyn.

458 Ninth Street.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

TRYPTOPHAN TEST FOR CANCER

To the Editor:—Please give the technic of the test for cancer of the stomach with bromin, referred to in THE JOURNAL, Sept. 9, 1911, p. 928.
W. W. SCOTT, M.D., Walhalla, N. D.

ANSWER.—The tryptophan test referred to depends on the power of ferments present in the cancer juices to break down proteins into amino-acids. Tryptophan is an amino-acid which is split out of the protein molecule by trypsin and by the autolytic enzymes of tissue cells, whether they be normal or cancer cells; but the pepsin of normal gastric juice does not disintegrate proteins as far as the amino-acids, and hence tryptophan is not found in normal stomach contents. When disintegrating cancer-tissue is present in the stomach, autolytic enzymes may be present in the gastric contents and may set free tryptophan from the digesting protein. If it has not been already formed, it is necessary to add a compound of tryptophan, glycyl-tryptophan, to the filtered stomach contents and incubate for twenty-four hours before testing. During incubation the glycyl-tryptophan is split into glycin (amino-acetic acid) and tryptophan.

The test for tryptophan is made by adding bromin water to the suspected liquid. Bromin water is obtained by shaking distilled water with bromin or letting it stand in a closed bottle, in the bottom of which a small amount of bromin is placed. The bromin water should be added cautiously, drop by drop, as an excess of bromin may easily obscure the characteristic color. The addition of a few drops of bromin water to 3 or 4 c.c. of the incubated stomach contents, to which a few drops of 3 per cent. acetic acid have been added, will give a reddish violet color if tryptophan is present.

The tryptophan reaction is not characteristic of cancer unless the possible presence of the proteolytic ferment of the pancreas or intestine is excluded.

PLOMBIERES METHOD OF COLONIC IRRIGATION

To the Editor:—Please give a short description of the Plombières method of colonic irrigation or tell me where I can find an article in English giving the method.
H. L. WILDER, Glen Rose, Texas.

ANSWER.—Dr. Bottentuit, consulting physician at Plombières (*Brit. Med. Jour.*, June 27, 1903), gives, in addition to dietetic and medicinal treatment, directions for using the waters at Plombières. He recommends baths highly, especially when given with the water. In addition he recommends enemas of this water, which should be given at a temperature of from 100.4 to 113 F. (38 to 45 C.) and from a vessel at a height of from 16 to 20 inches (40 to 50 cm.) above the patient's bed. He usually injects a pint at a time. Care must be used to inject it slowly and cause the patient to change position so as to bring it in contact with all parts of the colon. The enemas are best given after the bowels have moved, and after the first pint is rejected the patient should rest a short time and then receive a second enema. In an article on membranous colitis, Michael G. Foster (*Edinburgh Med. Jour.*, 1901) states that the hot alkaline baths at Plombières are often beneficial, their value depending more on their method of employment than on the chemical composition of the water.

HAIR DYES

To the Editor:—In answer to a correspondent (THE JOURNAL, Aug. 26, 1911, p. 757), you speak of eruptions due to hair dye. In one week this year I had three cases, one caused by eau-sublime, and two by "Empire Hair Regenerator." One of the patients asked me for a harmless hair dye. Can you suggest one?
E. HOCHHEIMER, New York.

ANSWER.—All hair dyes are harmful. Probably the following, recommended by Kaposi, are as safe as any:

To obtain a black color,

℞

	Gm. or c.c.		
Argent. nitrat	1		gr. xv
Ammon. carb	1	or	gr. xxij
Unguent. adipis	30		℥ j

M

Or,

℞

Argent. nitrat	4		ʒ j
Plumb. acetat	1	or	gr. xv
Aq. Cologn	1		gtt. xv
Aq. ros	ad 90		ad f℥ iij

M

ACID FRUITS MAY BE TAKEN AFTER CALOMEL

To the Editor:—Is there any scientific basis for the popular prejudice against eating acid fruits or other acids after a dose of calomel? If so, please explain.
LINDSAY PETERS, M.D., San Juan, P. R.

ANSWER.—1. Calomel is not acted on to an appreciable extent by non-oxidizing acids, such as hydrochloric or the fruit acids, except that it is affected by very concentrated boiling hydrochloric acid. It is converted by nitric acid and by other oxidizing acids from a mercurous into a mercuric compound which may produce irritating or poisonous effects. The tendency to this change is in proportion to the concentration of the acid. Probably little change would be effected by therapeutic doses of diluted nitric acid, when taken into the stomach. Calomel is changed in the presence of soluble iodids or bromids, and, to some extent, when in contact with concentrated solutions of chlorids, into metallic mercury and a mercuric compound.

The fear of an action of acids or acid fruits on calomel in the stomach is, therefore, quite unfounded and the same is probably true of the administration of chlorids in ordinary concentration following calomel. The simultaneous use of nitric acid, iodids or bromids should be avoided.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Oct. 7, 1911.

Gunckel, George I., reported for duty at Columbus Barracks, Ohio.

Bewen, A. S., lieut., left San Antonio, Texas, en route to Fort Snelling, Minn.

Wadhams, S. H., major, returned to Fort Slocum, N. Y., from leave of absence.

Casper, Joseph, lieut., returned to Fort Du Pont, Del., from sick leave and departure Sept. 28, 1911, en route to Manila, P. I.

Reynolds, C. R., major, returned to Washington Barracks, D. C., from leave.

King, Charles T., lieut., assigned to duty as surgeon of the transport *Sherman*, with station at San Francisco.

Darby, Taylor E., lieut., left Fort Sam Houston, Texas, en route to Manila, P. I.

French, S. W., lieut., M.R.C., reports for temporary duty at Fort Hancock, N. J.

Bernheim, J. R., dental surgeon, left temporary duty at Columbus Barracks en route to Fort Sheridan, Ill.

McAlister, John A., dental surgeon, on completion of temporary duty at Camp E. V. Sumner, Cloudcroft, N. M., ordered to Fort Bliss, Texas, for temporary duty.

Ford, Clyde S., major, returned to Fort W. H. Harrison, Mont., from leave of absence.

Kirkpatrick, Thomas J., major, reported for duty at Fort Adams, R. I.

Phalen, James M., captain, reported for duty at New York City as attending surgeon.

Fox, James S., lieut., left Fort Sam Houston en route to Philippine Islands for duty.

Edie, Guy L., lieut.-col., orders so amended as to assign him to duty at headquarters, western division, San Francisco, pending departure of transport to Philippine Islands, about Nov. 6, 1911, instead of Oct. 5, 1911.

Bierbower, H. C., lieut., reports arrival at Fort Robinson, Neb.

De Quevedo, F. G., M.R.C., relieved from active duty in Medical Reserve Corps.

Bernheim, J. R., dental surgeon, reports his arrival at Fort Sheridan, Ill., from Columbus Barracks.

Smith, L. L., captain, reports departure from army medical school on four months' leave.

Richard, Charles, reports his arrival at Walter Reed General Hospital, for duty as commanding officer.

Smith, lieut-col., left Fort Sam Houston for Fort Snelling, Minn.

Hart, W. L., lieut., granted two months' leave of absence, to take effect about Oct. 12, 1911.

Bartlett, W. K., captain, leave of absence granted him Sept. 25, 1911, is extended one month.

Geddings, E. F., major, reports his arrival at Fort Snelling, Minn., for duty.

Appel, D. M., colonel, reports his arrival at Fort Sam Houston, Texas, from leave of absence.

Medical Corps, U. S. Navy

Changes during the week ended Oct. 7, 1911.

Hayes, O., A. A. surgeon, appointed acting assistant surgeon from Sept. 29, 1911.

Hathaway, G. S., P. A. surgeon, detached from the naval station, Olongapo, P. I., and ordered to the *New Orleans*.

Allen, D. G., asst. surgeon, detached from the *Elcano* and ordered to duty at the naval hospital, Canacao, P. I.

Bass, J. A., asst. surgeon, detached from the *Saratoga* and ordered to the naval station, Olongapo, P. I.

Hart, S. D., asst. surgeon, detached from the *Barry* and ordered to the *Elcano*.

Traynor, J. P., surgeon, detached from the navy-yard, Boston, and ordered to the *Dolphin*.

McLean, N. T., P. A. surgeon, detached from the *Dolphin* and ordered home to await orders.

Curl, H. C., surgeon, detached from the naval hospital, Canacao, P. I., and ordered to the naval hospital, Mare Island, Cal

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF POST-GRADUATE WORK, CONTRACT PRACTICE, LEGISLATION, MEDICAL DEFENSE, AND OTHER MEDICOLEGAL AND ECONOMIC QUESTIONS OF INTEREST TO PHYSICIANS

A NATIONAL DEPARTMENT OF HEALTH

In a recent issue of *LaFollette's Weekly*, the personal organ of Senator Robert M. LaFollette, appeared an editorial on "Government Care of Public Health," a part of which is reprinted for the benefit of readers of THE JOURNAL.

"The speech of Senator Works of California from the standpoint of a Christian Scientist in opposition to the bill so ably championed by Senator Owen, has attracted wide attention to the subject of establishing a national department of public health.

"We must concede that if one believes there is no such thing as sickness or disease, then all scientific research into cause and prevention, quarantine and sanitation laws, and crusade against carriers and sources of contagion, must appear useless.

"But if we believe disease and sickness deplorable facts in human life, just as we believe health and vitality desirable conditions, then we must be anxious that the work done by our government for these objects should be encouraged, correlated, and brought to the highest efficiency.

"If we want pure food, cold storage conditions regulated, mosquitoes, flies, rats and other carriers of fever and plague exterminated; if we want the spread of tuberculosis, meningitis, and children's diseases stopped; if we want child labor laws, limitations of hours of women's work, proper health conditions in our public schools, then we should favor a national department of health.

"Scattered through all the various departments, State, Army, Navy, Interior, Agriculture, these subjects are now being considered in various ways. I pick up at random from my desk a report of the Marine Hospital. It relates to plague prevention work—cholera, leprosy, small-pox. It publishes municipal ordinances, pertaining to public hygiene, care of milk, protection of foodstuffs, garbage collection, sanitary and plumbing code. One report of the Department of Agriculture is a treatise on the extermination of hydrophobia; another relates to 'How Insects Affect Health in Rural Districts.' The latest report from the Bureau of Education is a volume on schoolhouses in their relation to health.

"It seems to me a reflection on our national intelligence and a commentary on our commercialism that the nations of Europe should have departments of health and education and we should be content to have these great fundamental subjects scattered about in different bureaus, as though they were of secondary importance in our national life.

"The opinion seems to have gained wide credence that the department is to be organized to promote some school of medicine. Nothing could be more erroneous. Mr. George H. Shibley, a resident of Washington in high standing, devoted to public interest, whose wife is one of the ablest osteopathic physicians in the country, made this statement to the Senate committee holding hearings on the bill:

"'It being a settled fact that the control of the licensing system is in the states, and there being in the states no tendency to surrender that power, it follows that the osteopathic physicians, the homeopathic physicians, and the eclectic physicians, whose occupations are licensed under state laws, are in no danger from a national health department. . . . The need for the establishment of a national health department is most pressing. The people are less protected from disease and death than are their cattle and hogs. A properly conducted department of health can do for the people in general what the Department of Agriculture is doing for the farmers. All of the people are vitally interested in the proposed department, while only about one-half of them are directly interested in the Department of Agriculture.'"

"I DRINK TO THE GENERAL DEATH OF THE WHOLE TABLE"

GRADUATE COURSE

Second Month — Second Weekly Meeting

FRACTURES OF VAULT OF CRANIUM

VARIETIES: Fissured, fragmented, comminuted, perforated, simple and compound. Fracture of inner or outer table alone. Depression, central and peripheral.

Mechanical principles involved "bending" and "bursting" fractures. Lines of fractures.

PROGNOSIS: Depends on brain injury and infection. Extent of injury, area of brain involved, degree of depression, simple or compound fracture. Remote effects, headache, epilepsy and insanity.

TREATMENT: (1) Fracture without depression and without cerebral symptoms, (2) with depression, (3) with cerebral symptoms, (4) compound fractures.

FRACTURE OF BASE OF CRANIUM[1]

PATHOLOGY: Usual points of impact, beginning points of fracture, line of fracture, transverse, longitudinal, diagonal, circular. Effects of bilateral and unilateral compression. "Counter-stroke."

DIAGNOSIS: (1) History of character of blow or injury, site of impact, etc. (2) Ecchymoses—In eyelids, about eyes, mucous membrane of pharynx, mastoid region, post-cervical region. Time of appearance. Differentiate from local injuries. (3) Flow of brain tissue, blood and serous fluid—In external auditory canal. From nose. From pharynx. Significance of each. Differentiate in case of hemorrhage. (4) Disturbance in function of cranial nerves. Forms of injury. Sites of injury.

TREATMENT: Disinfection of aural and nasal cavities. Drainage. Removal of fragments. Rest.

DIFFERENTIAL DIAGNOSIS OF "CONCUSSION" AND COMPRESSION OF BRAIN: (1) Onset of symptoms, (2) special senses, (3) respiration, (4) pulse, (5) nausea and vomiting, (6) bowels, (7) bladder, (8) deglutition, (9) voluntary muscles, (10) pupils, (11) prognosis.

COMING MEETINGS

American Association of Railway Surgeons, Chicago, Oct. 18-20.
Kentucky State Medical Association, Paducah, Oct. 24-26.
Medical Society of Virginia, Richmond, Oct. 24-27.
Mississippi Valley Medical Association, Nashville, Tenn., Oct. 17-19.
Southern Medical Association, Hattiesburg, Miss., Nov. 14-16.

MICHIGAN STATE MEDICAL SOCIETY

Forty-Sixth Annual Meeting, held at Detroit, Sept. 27-28, 1911

The President, DR. C. B. BURR, Flint, in the Chair

Officers Elected

The following officers were elected for the ensuing year: President, Dr. D. Emmett Welsh, Grand Rapids; vice-presidents, Drs. Guy L. Connor, Detroit; Neal S. McDonald, Hancock; George C. Hafford, Albion; George D. Carnes, South Haven; secretary-editor, Dr. Wilfrid Haughey, Battle Creek; delegate to American Medical Association for two years, Dr. E. T. Abrams, Dollar Bay; alternate, Dr. Arthur D. Holmes, Detroit.

Resolutions were adopted expressing satisfaction and pride in the work of Dr. Wiley and commending the action of President Taft in supporting him.

Paranoia and Certain Paranoid Conditions in Their Relations to the Public and the Profession

DR. C. B. BURR, Flint: The identification of paranoia as a distinct form of insanity marks a psychiatric advance. It has been a useful classification, but like many others subserving an important end has been very much overloaded. While thirty years ago the term was not in frequent employment even among psychiatrists, it is now commonly used by everyone, and its definition is stretched to cover a multitude of faults of disposition, eccentricities, and temporary or permanent departures from conventional standards of thinking, feeling and acting. It has been found a convenient cloak to shield from punishment, and it seems important that a clear understanding of its fundamental character should be presented to the medical profession, the members of which themselves often employ the term loosely and without regard to consistency.

Briefly, this is a non-dementing form of disease of slow and insidious development. It is the outgrowth of a morbid personality, and evolution of a crooked stick. Its delusions are logically evolved from false premises, and in their defense the individual is sagacious and shrewd. Its life history is consistent and its progress marked by certain well-defined epochs. There are: first, the incipient period; second, the persecutory period; third, the period of developed and logical delusions. In contrast with this form of disease is the paranoid form of dementia præcox. The existence of dementia præcox implies early reduction of brain force and hereditary tendency—the neuropathic organization—is an important factor in its development.

There are included in the designation dementia præcox, various forms of disease described under old-time classifications, as the insanity of pubescence, insanity of masturbation, ovarian insanity, katatonia and stuporous melancholia. Perception and memory may be acute, but reasoning and judgment are not correspondingly developed. These patients are in infancy erratic, hysterical, impulsive, and lacking in inhibitory control. They are subject to headache and frequently break down under school pressure. There are not infrequently encountered among alcoholic cases those showing delusions of suspicion, or persecution, or extravagance. The overweening self-confidence, a marked quality of the habitual tippler, goes over with no lack of readiness into an absurd self-appreciation and extravagance of thinking and doing. Ideas of persecution develop, and it is not difficult to believe that the individual's self-criticism is a basal fact in the impression that the outside world is censorious. Similarly the connection of certain manifestations in these cases with sexual wasting is readily established.

A paranoid condition from alcoholism is differentiated from the foregoing insane state by: 1. The presence of a definite provocative factor—alcoholic indulgence. 2. The existence of delusions of persecution and infidelity, possibly also those of an expansive character, all quiescent under abstinence from drink, lighted into extreme activity by the inebriating. 3. The tendency toward recovery under well-directed treatment.

Problems in the Diseases of the Thyroid

DR. CHARLES H. MAYO, Rochester, Minn.: Disease due to lessened secretion of the thyroid is brought about by a thinning of the secreting epithelium in the presence of colloid or other retained secretion, even though the actual size of the gland may be increased enormously. In operating on such glands it is advisable to leave some of the tissue next to the capsule, for the tissue on the surface of the gland retains its powers of producing the internal secretion. Frequently thyroids which have been in this state of lowered secretive power suddenly become hyperactive, and often symptoms of Graves' disease develop. This is brought about by a development of epithelial gland cells growing into the colloid filling the ascini in the gland. Such sudden development of exophthalmic symptoms is usually attributed to some recent occurrence such as a fall from a horse, or a severe shock. The accident may have something to do with the sudden development of the symptoms, but the patient has been in a state where the body was barely able to take care of the extra secretion, and the exophthalmic symptoms were only awaiting a chance to light up.

In the case of patients in too poor physical condition for operation, I advocate the tying of one or more of the thyroid arteries. This is not a harmless operation, for I have lost three patients out of thirty-seven following this operation.

After tying the vessels, there is a discharge of thyroid secretion (internal) which almost overwhelms the patient. As soon as the diarrhea and other severe symptoms are over—about a week—the gland should be removed, for then the patient is in the best condition. The gland is empty of internal secretion, and the operation is much safer than if one waits until the gland has an opportunity to recover from the first active discharge. Practically all the thyroid cases, outside of those between the ages of fifteen and twenty-three, or during pregnancy, are surgical. During these two periods of a woman's life it is natural for the thyroid to enlarge somewhat.

In all other cases the surgeon should be consulted early. Graveyards are filled with people who have been treated medically and then rushed to the surgeon as a last resort. In such cases, if blood has been drawn, the patient "died of an operation," not of the disease, or of the medical treatment. The surgery of the thyroid gland is constantly improving, but advance has been at the cost of many lives that we are now able to save. Twenty-five per cent. of these patients will recover symptomatically, 25 per cent. will die no matter what the treatment, which limits us to the middle 50 per cent. in our surgical work, and we can save about half of these.

(To be continued)

INTERNATIONAL MUNICIPAL CONGRESS AND EXPOSITION

Held in Chicago, Sept. 18-30, 1911

(Concluded from page 1229)

Disposal of Garbage

Dr. A. F. Storke, Oak Park: Garbage should be collected every day, if feasible, or at least every other day; garbage should not be fed to hogs; it is not rich in nitrogenous matter and is a poor fertilizer and should not be used for that purpose; it should be burned at a temperature of 1,250 F., or over. If a municipality is so equipped that it can reduce refuse, a considerable return can be made thereby on the money expended. Garbage should be burned in household burners if the latter are properly cared for and maintained. Garbage should not be placed on dumps, or thrown on the ground. Flies can be kept away from garbage by having the garbage drained, wrapped in paper and put in cans, and the cans kept as reasonably clean as other articles in the kitchen. Garbage should be hauled in tight metal carts, with the tops kept down at all times.

In 1909 an eight-furnace incinerator was constructed in Oak Park, capable of handling 50 tons of garbage a day. This incinerator required for collection of garbage and its care five men, five horses and two carts. The incinerator handled 5,033 tons of garbage at a total cost of about $1.75 a ton. About 200 pounds of coal is used to a ton of garbage consumed.

Dr. Samuel Greeley, superintendent of garbage disposal of Milwaukee, described the Milwaukee refuse incinerator which is designed to handle 300 tons of mixed refuse, that is, garbage, ashes, rubbish, in 24 hours. The ingredients are mixed on a floor above the furnace and then discharged into the furnace by a mechanical stoker. The temperature ranges from 1,200 to 1,600 degrees F. He found that a mixture of 60 per cent. garbage and 40 per cent. ashes and rubbish will burn at a temperature above 1,200 degrees. The cost of operation is varied from 86 cents to $1.05 a ton, depending partly on the labor and the quantity of garbage and refuse handled. When more refuse is delivered to the plant it can be handled more economically than in smaller quantities.

Cost of Health Department Per Capita

Mr. C. B. Ball, chief sanitary inspector of Chicago, presided over this section. He discussed the cost of health department work and whether school inspection, tenement inspection, building plan inspection, tuberculosis work, and garbage collection should be charged against health work cost.

Dr. Gottfried Koehler, assistant health commissioner of Chicago, quoted the address of Dr. Evans, in which he said: "A health department in Chicago costing 25 cents per capita can hold the gross death-rate under 16 per 1,000 for a few years. It can hold the number of deaths from diphtheria at about 800 (3.75 per 10,000); from scarlet fever at about 600 (3.50 per 10,000); typhoid at about 300 (1.33 per 10,000), and baby deaths from summer complaint at about 3,000 (1.4 per 10,000). It can keep small-pox epidemics about 12 years apart and paralyzing epidemics of diphtheria or scarlet fever about four or six years apart."

"A health department spending 50 cents per capita should put diphtheria down to, say, 100 deaths per year; scarlet fever to about 500; typhoid to 120; and cut off 5 per cent. from the tuberculosis mortality. It should be able to add ten years to the small-pox intervals, and three or four years to the diphtheria and scarlet fever intervals." He said that, in addition, he believed the infant mortality could be reduced to 2,500 or less; that accidents at birth, and blindness could also be materially reduced; that venereal diseases could be lessened and following this would come lessening of organic cardiovascular and nervous diseases.

A health department costing one dollar per capita could accomplish and improve the conditions before stated and materially improve the sickness rate from colds, pneumonia and tuberculosis. The living and working conditions could be improved so that the mortality, morbidity and incapacity from impure-air and occupational diseases would be materially reduced. Nutritional diseases of infancy and childhood could be dealt with so that a saving of 25 per cent. in the death-rate would result.

Again quoting Dr. Evans: "A $3.00 per capita health department would cause small-pox to recur only at very long intervals; diphtheria to disappear as an endemic disease; the typhoid rate to fall from its present rate, 15 per 100,000 to 1 or 2 per 100,000; would cut the rate from tuberculosis to one-half its present figure; decrease the loss from colds by one-third; increase the efficiency of the school child 20 per cent.; increase the efficiency of labor, say, 10 per cent.; accomplish nearly as great an improvement in efficiency of human effort and in health conditions over the conditions now prevailing as the $3.00 per capita health administration in the Panama Canal Zone has increased health security and efficiency over that which formerly prevailed there.

"A $10.00 per capita health administration continued for fifteen years should eliminate tuberculosis, small-pox, diphtheria, and typhoid; should greatly lessen scarlet fever; should halve the baby death-rate; should halve poverty and materially decrease crime; should increase the efficiency of labor materially."

Dr. Koehler stated that hospitals for communicable diseases, dispensaries and clinics for contagious and communicable diseases, including venereal diseases, and ambulances for communicable diseases should be charged to the cost of health department work.

AMERICAN ROENTGEN RAY SOCIETY

Twelfth Annual Meeting, held in Richmond, Va., Sept. 20-23, 1911

(Continued from page 1230)

Duodenal Diagnosis

Dr. E. H. Skinner, Kansas City, Mo.: We have been able to base a mechanical diagnosis of duodenal ulcer on the following: When a bismuth and water suspension is swallowed by a fasting patient, it readily passes the pylorus into the duodenum (because the acid stomach content is not taken up as when food is offered the stomach, neither is there a closure of pylorus as when a food bolus is swallowed). The stomach appears normal after the ingestion of a bismuth meal (2 ounces of bismuth oxychlorid to 13 ounces of wheat porridge), but there is a vigorous peristalsis and a rapid emptying of the stomach in as short a time as one-half hour, and at least in two hours. The duodenum seems to be sluggish and casts a shadow for a longer interval than usual, but the food rapidly traverses the remaining portion of the small intestines. By this method of filling the duodenum there may be found present an hour-glass contraction at the site of the ulcer. Usually, the duodenum is sluggish and does not exhibit any pronounced peristalsis. When the duodenum is filled and pressure is made at the outer curve of the duodenum, as shown by the shadow, the patient usually experiences some pain or discomfort. I place the greatest weight on the rapid emptying of a stomach that exhibits the usual normal J-shaped shadow and a vigorous peristalsis.

The Roentgen Rays in Neurasthenia

Dr. Arthur Holding, Albany, N. Y.: Neurasthenia and other neuroses are often caused by conditions which do not have their origin in the nervous system, and which may be detected by the Roentgen ray; therefore, it is advisable that all these patients be examined thoroughly by a competent Roentgenologist. A few illustrative cases are the following: Case 1. Obscure progressive paralysis of the arm, shown by the Roentgen rays to be due to a supernumerary rib. Case 2. Epileptiform convulsions, shown to be caused by unerupted teeth. Case 3. A very obscure gastro-intestinal condition due to cardiospasm. Case 4. Neurasthenia with obscure constant pain caused by hour-glass contraction of the stomach. The patient was regarded as a neurasthenic for twenty years. Case 5. Auto-intoxication with nervous prostration, regarded as a case of neurasthenia due to visceroptosis. Case 6. Neurasthenia proved to be a case of tuberculosis of the lungs. Case 7. Neurasthenia cured by the removal of a stone from the kidney. Case 8. Patient unable to walk because of pain in the feet and legs. Thought to be due to a broken-down arch. The Roentgen ray showed an arteriosclerosis in the arteries of the feet and determined the case to be one of intermittent claudication. Case 9. A painful condition of the wrist supposed to be a neuritis, shown, however, to be caused by tuberculosis of the bones. Case 10. Severe case of neurosis which proved to be caused by a dislocation of the symphysis pubis.

Dental Defects as a Cause of Epilepsy

Dr. Henry K. Pancoast, Philadelphia: I wish to call attention to the importance of including a careful examination of the teeth as a part of the general routine examination of all cases of idiopathic epilepsy. Dental defects may exist and be responsible for the epilepsy. In three cases examined by me such defects proved to be etiologic factors because when they were remedied the patient was free from epileptic attacks. Such defects may exist without any clinical manifestation; in fact, that is the rule; therefore, it is advisable in all cases of epilepsy to include as a part of the routine examination of the head a careful examination of the teeth. This is especially important in the case of children, although cases have been discovered in adults where the epilepsy was caused by dental conditions. Any defects found must be remedied early, in order to do any good, as they are usually, perhaps, only a contributing factor in the etiology of the condition. Moreover, in view of this fact there should be no relaxation in the vigorous application of any other therapeutic measures that have been practiced, or which may be indicated.

Discussion on Papers of Drs. Holding and Pancoast

Dr. E. H. Skinner, Kansas City, Mo.: I once heard a man speak against machine-made diagnoses, and yet diagnoses made by mechanical means are superior to mere gray-matter diagnoses. The thermometer, microscope, Roentgen ray and blood-pressure apparatus have superseded less accurate and exact aids in diagnosis. Many cases of gastro-intestinal disturbance have been diagnosed as neurasthenia until the Roentgen ray disclosed an ulcer of the stomach, which was substantiated by a careful inquiry into the history of the patient. The gastro-enterologist claims that gastroptosis is the cause of neurasthenia, while the neurologist holds that neurasthenia is responsible for the gastroptosis. The Roentgen ray will often disclose a condition which, if corrected, will dispel the neurasthenia.

Dr. George C. Johnston, Pittsburgh: As for neurasthenia being caused by unerupted teeth, it is probably true that there is some connection between the irritation of impacted teeth or any other constant irritation and epilepsy—but only in the case of an individual who is going to have epilepsy anyway. For three or four years I have examined cases of impacted teeth removed by two extraction specialists, but I have yet to see a single instance of epilepsy from this cause. As for neuralgia: I was asked to examine a gentleman who had been suffering intensely from tic douloureux for a long time. Careful examination with the Roentgen ray finally disclosed a little area of caries just under the gum margin, in which there was a tomato seed. When that was removed the neuralgia ceased, and it has not returned since. In another case the nervous disturbance was due to abscessed incisor teeth.

Dr. George E. Pfahler, Philadelphia: I was asked to examine a woman who had a neuralgia in her right foot. The neurologist who referred the lady to me scouted the idea that the neuralgia might be caused by an abscessed tooth, although I had found two such teeth in the roentgenogram. Two years later another physician referred the patient to a dentist, who treated these two teeth, and the neuralgia promptly disappeared.

Dr. Clarence E. Coon, Syracuse, N. Y.: At the age of 17, a man began to have attacks of epilepsy which increased in severity and frequency until his mind became affected. His family finally had to place him in an asylum for the insane. He became violent and unmanageable. I was asked to examine him and found four impacted wisdom teeth, which I advised to have extracted. This was done, and from that time on this man has not had a single attack of anything like epilepsy. Within two weeks after the operation he was rational and quiet. He gained rapidly in weight, and is now entirely well.

Dr. Henry K. Pancoast, Philadelphia: I would not want to create the impression that I believe that epilepsy is solely caused by impacted teeth, or other dental conditions. In epilepsy, as in any other disease, perhaps more so, you must have the soil in which the seed can develop. It is particularly in those cases where the dental conditions do not give rise to clinical phenomena that we must include the mouth and teeth in our examination. But this is only one factor which may cause the epilepsy.

Roentgen Diagnosis of Position in Pregnancy

Dr. P. M. Hickey, Detroit, Mich.: It is possible to make a Roentgen diagnosis of the position of the fetus in utero without apparent injury to the mother or fetus. The differential diagnosis between single and multiple pregnancy can be made with certainty. The cases I investigated went on to term and normal delivery. Careful examination of the child failed to reveal anything indicative of damage done by the ray.

(To be continued)

ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES

Twentieth Annual Meeting, held in Milwaukee, Sept. 26-29, 1911

(Continued from page 1229)

Award of Association Prize

The first annual award of the prize of $200 presented by the association for the best essay submitted in competition on the subject "What Are the Best Available Measures to Diminish Venereal Disease Among Soldiers and Sailors, and Along What Line Should We Seek the Cooperation of the Federal, State and Municipal Authorities?" was made for the essay presented by Captain Edward B. Vedder, M.C., U. S. Army, who after noting the importance of the question of the prevention of venereal diseases and the ineffectual methods thus far adopted to prevent or limit them, made the following recommendations: 1. Reestablishment of the canteen. The author believes that the absence of the canteen has promoted intemperance, and as soldiers will continue to use alcoholic beverages even as civilians do, if drinking within the post is barred, they will go outside to disreputable houses, and many will become victims of prostitutes. 2. The compulsory and universal adoption of the following measures in the military services: (a) Organization of soldiers' and sailors' clubs to provide legitimate amusement for the men. (b) Instruction for every man in the services on the subject of venereal disease, by a well-written and illustrated pamphlet on the subject, on which the recruits should be required to pass a simple written examination before being sworn into the service. (c) Approved methods of personal prophylaxis after contact by thorough washing of the genitalia with soap and water followed by 1-2000 bichlorid; injection of 10 per cent. argyrol solution into the urethra and inunction with 33 per cent. calomel ointment; this treatment to be given at hospital, or from packet carried by the soldier. Every man returning from pass should be obliged to report at the hospital, state whether he has exposed himself to venereal infection and whether he has used the packet. If he has not used the packet, he will be given the prophylactic treatment. If he states that he has not exposed himself and subsequently develops venereal disease, he will be tried by summary court. (d) Physical inspection which has already been tried, but without great success in many cases. Inspection should be unannounced and unexpected and every medical officer in the post should take part in the inspection. (e) The venereal register. This register which is generally kept at the hospital, at present, should go with the man when he is transferred to another post or another ship. This will require a change of existing regulations, as the surgeon, who alone has these histories, is not informed when the man is transferred. This would prevent many readmissions, some of which are carried at present "in line of duty" because of this lack of previous medical history. 3. Stoppage of pay. This is the logical punishment for those men, who with the above recommendation in force, still contract venereal disease, and is intended chiefly to compel men to use the prophylactic. Statistics show that 7.5 per cent. of all men fail to report on return from liberty and 18.8 per cent. of the total number of venereal diseases in the sick reports may be attributed to this cause. Another large percentage is due to denial of venereal exposure.

These measures are applicable in both Army and Navy, and are independent and each essential to success. For this reason he believes that all these methods should be universally enforced by War and Navy Department orders. Congressional action would be necessary for the reestablishment of the canteen, the obtaining of appropriations for men's club houses, and the enactment of a law providing for stoppage of pay while on sick report on account of venereal disease not contracted in line of duty.

He next took up the cooperation desired with the federal, state and municipal authorities and suggested as regards the federal authorities that the services should do all in their power to further the appeal now before Congress for a national department of public health, which could make a thorough study of the subject of venereal diseases in the United States; that the federal authorities should be asked to take more severe measures than have yet been adopted for the suppression of the interstate and international traffic in white slaves by which the ranks of the prostitutes are largely recruited and that the postoffice authorities should be asked to deny the privilege of the mails to the fraudulent mail order concerns that advertise to treat venereal diseases. The state and municipal authorities, he suggests, should adopt the following measures: Compulsory notification of venereal diseases which can be studied and controlled, by knowing where the cases are; segregation, inspection and treatment of prostitutes found to be diseased; abolition of liquor selling in houses of prostitution, and of soliciting on the streets, and the education of the young of the land in matters of sexual physiology and hygiene.

Captain Vedder acknowledged that none of the measures recommended was ideal and that the elimination of venereal diseases could never be obtained until human nature is quite altered, but he argued that the adoption of the measures recommended would undoubtedly result in a considerable reduction in the incidence of these diseases.

Dementia Præcox and Alcoholism

Captain L. L. Smith, M.C., U. S. Army, after a thorough discussion of this question, including a careful study of the literature, believes that this subject is most important from the standpoint of the military surgeon, as dementia præcox is the most frequent form of mental disease observed in patients admitted from the military service to the Government Hospital for the Insane. In the fifty-nine cases which the author analyzed, it was noteworthy with what frequency alcoholism was given as an etiologic factor in the production of this form of psychosis. Indeed, in the early stage of the disease, it was not always possible in these cases of dementia præcox combined with alcoholism, to make an accurate diagnosis. The history of the patient, especially if he had been sent to the hospital from remote military posts, would often indicate that the prominence of the alcoholic symptoms at the onset of the psychosis had resulted in a diagnosis of an alcoholic psychosis. In the fifty-nine cases studied there was a history of alcoholic excesses in 21 cases, or 35.6 per cent., and 6 or 10 per cent. were mixed cases of alcoholism and dementia præcox. Acute and subacute alcoholism, more frequently complicated these cases than the chronic form. The cases of chronic hallucinosis in which the alcohol may act as a disintegrating factor, frequently turn out to be dementia præcox.

Military Absenteeism in War

Major Edward L. Munson, M.C., U. S. Army: The medical department in war is charged with the administration of the sanitary service, and especially with the methodical disposition of the sick and wounded, so as to insure the retention of those effective, and relieve the fighting force of the non-effective. While the army surgeon remains a doctor in respect to his usefulness in the field of professional service, he must exercise his restorative effects with ailing individuals toward an end, the purpose of which is essentially military and not humanitarian. At the beginning of the Civil War, five soldiers were present for about every one absent. A year later three were present for every one absent. In the third year, two and one-half, and in the final year, less than two men opposed the enemy for every man absent. Though this grave proportion of absentees received the early attention of the military authorities and military measures were taken for its prevention, it continued to increase despite of all efforts until more than one-third of the armed land forces of the United States were absent from the colors and beyond military control, and to this absenteeism officers particularly contributed.

Absenteeism may be regarded in general as an expression of dissatisfaction with military service and conditions, as the statistics show that in the Federal Army in commands of an average effective strength of 662 men, 258 were absent from cause rather than illness, and only eighty by reason of sickness in hospital. Factors were a low standard of discipline, and improper location and management of general hospitals, most of which were far distant from the seat of military operations, and were under management of civilian physicians, or under state control, instead of being under the exclusive control of the Medical Department of the Army. Another factor was wrongful admission of soldiers to sick report. Malingering does not appear on the records of the Civil War with 6,454,834 admissions to sick report, nor on the records of the Spanish-American War with 317,195 such admissions. The first aim of a malingerer is to be enrolled on the sick report, the second, to be separated from his regiment and sent to a general hospital, from which he then secures, by favor or political influence, a sick furlough, and once at home, certificates of physical disability are unfortunately easy to be obtained.

At the outbreak of the Civil War, there were only eighty-one medical officers of the regular establishment available for duty with troops and this was insufficient to leaven the mass of 14,000 civilian medical men employed in various professional capacities during the war. These latter were as a rule not accustomed to the detection and handling of cases of feigned disease. In the Spanish-American War a similar condition was found, so that it became necessary to issue an order absolutely putting it out of the power of any medical officer to legalize absenteeism by reason of sickness without the final approval of the officers. In the Philippine Islands orders prescribed that sick furloughs should be no longer granted on the recommendation of a single medical officer, but the individual should be sent to the Division Hospital, Manila, for observation and final recommendation by a carefully chosen board of medical officers.

Many men have been discharged from the military service on surgeon's certificate of disability. In the Civil War 223,525 were so discharged; a greater number than those who died of wounds—34,773, who died of disease—183,287, who deserted—199,045, or who were killed in battle—61,362.

The causes assigned for discharge were not convincing: 11,779 discharges were granted for rheumatism, 10,636 for heart disease, 16,185 for diarrhea; 14,500 for debility; 3,872 for epilepsy, 3,729 for bronchitis; 2,038 for varicose veins; 1,415 for varicocele and 1,598 for piles.

Remedies are: better discipline, abolition of political influence—a grave condition under our form of government—careful scrutiny of admissions to sick call, etc. Medical officers should always work in conjunction with line officers, as the latter know better the characteristics of the men in their command. The functions of the regimental dispensary which is intended to care only for emergency cases and the slightly sick or injured should not be used. Severe cases should always be transferred to the field hospitals. In the field hospitals undeserving patients who have been successful in evading duty and leaving their command may be halted in their progress toward the rear and home, and their escape thus prevented. The same applies to evacuation, base and general hospitals, where the diagnosis should be carefully scrutinized and doubtful cases reexamined and passed on by an independent medical board. Similar medical boards with similar powers of limitation of invalidism should be established at the limits of the various sanitary zones along the line of communication.

The various humanitarian relief societies may readily be perverted by designing individuals into innocent promoters of fraud. They should be under firm and tactful military control.

Dr. Munson's paper was a plea for a stronger, more businesslike administrative management of the medical department in time of war. He attempted to demonstrate the economic and military need of maintaining and training in peace the not inconsiderable number of medical officers required in time of war to maintain the strength and efficiency of commands; the utter chaos resulting from expectation that civilian physicians will appreciate and properly perform other than purely professional duty in time of war, and that, in addition to the humanitarian side of the work of the medical department, it has other obligations which form the very foundation of military efficiency and which, in time of war, need to be recognized by both line and medical officers in their true and paramount importance.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Twenty-Fourth Annual Meeting, held in Louisville, Ky., Sept. 26-28, 1911

(Concluded from page 1227)

Congenital Mucoid Multicystic Tumor of the Small Intestine

Dr. H. W. Longyear, Detroit: The tumor was about 2 inches in length, situated subperitoneally on the sides and mesenteric aspects of the small intestine, and was composed of an aggregation of small cysts, filled with mucus. The case was discovered accidentally during an appendectomy. The tumor was not removed, as it was apparently benign and causing no symptoms.

Diseases of the Thyroid in the Female

Dr. Miles F. Porter, Fort Wayne: Women are five times more prone to thyroid disease than men. The thyroid was originally a sex organ. The thyroid is especially active during the period of sexual activity, and increases in size during menstruation and pregnancy. The toxemia of pregnancy and puerperal infections are probably often due to inactivity of the thyroid. Goiter may be due to disease of the genital organs. Disease of the thyroid may cause amenorrhea, dysmenorrhea, menorrhagia, sterility, mental aberration, premature separation of the placenta and chlorosis. Goiter in the mother often produces bone deformities in the offspring.

DISCUSSION

Dr. William D. Haggard, Nashville: A few days ago I saw a woman with exophthalmic goiter who married last November, at the age of 30, and in January had marked enlargement of the thyroid, with tachycardia, tremor, and a beginning exophthalmos. She conceived in February and aborted in May. During her pregnancy her symptoms were considerably exaggerated, and an interesting feature was that these symptoms all subsided after the miscarriage. She still has a chronic hyperthyroidism which has recently become more active and for which I think a partial thyroidectomy will relieve her.

Dr. Hugo O. Pantzer, Indianapolis: I removed a fibroid tumor of the uterus, doing a unilateral oophorectomy in a woman who had at the time moderate Graves' disease. Within twenty-four hours after the operation this patient had a very conspicuous thyroid. The following morning I found that the thyroid had subsided completely so as to be no longer palpable. Nine or ten days afterward the patient developed bilateral trouble, and then had hyperthyreoidea in the worst degree from which she recovered only slowly within the next two months.

Dr. Albert Vander Veer, Albany: Ten years ago I removed a fibroid tumor from a woman 31 years of age. She had a marked enlargement of the thyroid. Her uterine appendages had been removed at the time with the fibroid, and she had gone along without any unpleasant symptoms. Ten years later she had all the marked symptoms of goiter, with hot flashes, etc. On examining her I found that the thyroid was slightly enlarged. She presented many of the symptoms of exophthalmic goiter. Her case cleared up nicely under the use of the thyroid extract, but the cause of the condition and the therapeutic remedy given for it were not clear to my mind.

Dr. Edwin Walker, Evansville: A number of years ago I had an experience along this line that made a deep impression on me. The patient came from a highly neurotic family; had suffered from epilepsy during her early life. At about puberty these attacks became worse, and a good deal of the time the patient was in the condition of status epilepticus, having from forty to sixty attacks a day. Bromids had no effect whatever on these convulsions. A few symptoms suggested the possibility of hypothyroidism. I fed her on partially cooked thyroids, and her recovery was remarkable and rapid. Whenever I would stop the administration of this thyroid extract there would be a return of the symptoms. I kept her on thyroid extract for a year or more. She has been under my observation since that time; she was 15 years of age then, and 35 years of age now, and she has been entirely relieved of her epilepsy.

Dr. Roland E. Skeel, Cleveland: Last year I saw a patient who was choking rapidly because of a rapid enlargement of the thyroid. She was eight months pregnant. She had an attack of dyspnea, and she had such a severe stridor that it could be heard across the corridor. She had an enormous thyroid which was removed under local anesthesia, and being fearful she might be delivered of an eight-months child, I ordered a small dose of morphin. After giving the morphin, she had very marked toxemia of pregnancy, so much so that the urine contained from 10 to 15 per cent. of albumin. This is contrary to what is observed under these circumstances. There was a rupture of the bulb of the jugular vein, and she died instantly. The house surgeon made a post-mortem Cesarean section and secured a living child. The child lived a few weeks, then died from ordinary marasmus.

Dr. William H. Humiston, Cleveland: We see many cases in which we have a rapid pulse and a great many symptoms that we are at a loss to account for, and examination of the thyroid shows no enlargement whatsoever. My experience in these cases has been that with the administration of the thyroid extract I have universally obtained good results.

Dr. Robert T. Morris, New York City: If we have a hypothyroidism, the thyroid extract furnishes a substance which is not furnished in sufficient quantity by the gland itself. If we have a hyperthyroidism, it often means that we have a compensatory hypertrophy of the gland which is under great demand, and in that case, if we give the thyroid extract we lessen the need for compensatory hypertrophy on the part of the gland, so that in certain cases of hyperthyroidism and incases of hyperthyroidism we use precisely the same therapeutic resource because of the two different groups of cases, but each case in itself becomes a study. In one case you will find with the *x*-ray alone you can overcome almost all of the symptoms of hypo- or of hyperthyroidism; in another case, with the thyroid extract you are using, while in another case you have to use both together, and in still another case you produce disastrous results with either one of the two.

Fibroids of Cervix

Dr. Lewis S. Smead, Toledo: Fibroid tumors of the cervix and uterine body below the movable peritoneum have not received the attention to which the great technical difficulties of their removal entitle them. The subperitoneal variety are most troublesome because of their immobility and the obliteration of landmarks they cause. Fibroid tumors of the cervix are found in about 5 per cent. of all women who have uterine fibroids. The tumor may arise in front, behind or at the side of the cervix, but the posterior growths are somewhat the most common. The physical characteristics of the tumors are not unusual, but the distortions of the pelvic organs, especially of the vagina and bladder, are common. The cervical tumors, because of their position and their immobility, are very likely to block the birth canal. Small fibroids on the anterior cervix, projecting into the base of the bladder, may simulate almost exactly the male prostate. The bladder is usually enormously elevated and enlarged by being stretched out over the tumor. The vagina is much elongated and crowded out of position. The rectum and vagina are much thinned by pressure atrophy.

The ureters may be pushed up by a tumor or pulled up by adhesions. They may also be blocked by pressure or kinking. The rectum and sigmoid are raised up by tumors arising beneath them. The position of the upper end of the vagina is usually the key to the situation, and an examination under ether will often locate it. The operative treatment is radical, rarely palliative. The operative removal requires the use of special operative maneuvers, such as bisection of the uterus and tumor, enucleation, and excision of a large wedge of the tumor, or the classical side-to-side hysterectomy. The principle of the Doyen hysterectomy can often be employed with profit. The cavity left is very liable to infection from the rectum, and will usually have to be drained, although in some cases it may be obliterated and the abdomen closed.

Early Diagnosis of Ectopic Gestation

Dr. R. R. Huggins, Pittsburgh: The diagnosis should be made previous to the final rupture and collapse in at least 80 per cent. of the cases. If a flow from the vagina begins in a period varying from four to five days to three weeks after the regular time, continuing more or less regularly, accompanied by pains periodic in character, located in the hypogastrium on either side, extrauterine pregnancy should at once be suspected by the physician, unless some other well defined condition is present to account for it. The vaginal hemorrhage may be dark-colored blood, coagulated at times; at others a blood-tinged leukorrhea, or in some instances bright red. This hemorrhage is doubtless due to a partial separation of the ovum from its cyst wall, or to the separation of the decidua from the uterus.

In ninety-five per cent. of the cases of ectopic pregnancy seen by me the history and local symptoms have overshadowed all others and seldom in the early weeks has there been present the general signs of pregnancy. Careful study of the history in fifty-two cases which had gone on to rupture in my own experience showed that in all but five there had been some irregularity of the normal flow and pain before the final rupture and collapse.

Interstitial Pregnancy

Dr. N. Stone Scott, Cleveland: There are three subdivisions: (1) External interstitial pregnancy, attended with danger, because rupture usually takes place into the abdomen before the sixth month; (2) middle interstitial pregnancy, and (3) internal interstitial pregnancy. The use of the curet is the etiologic factor in the production of many of them. So-called false perforations of the uterus are frequently interstitial pregnancies. The second variety begins as interstitial, develops into the uterus, and terminates normally.

DISCUSSION

Dr. James F. Baldwin, Columbus: Several years ago I reported six cases in which I made a diagnosis of ectopic rupture and operated.

Dr. Charles N. Smith, Toledo: The chief obstacle to early diagnosis in extrauterine pregnancy is the fact that a patient who is not suffering continuously or seriously does not consult a physician until the rupture has taken place.

Dr. E. Gustav Zinke, Cincinnati: The pathology of ectopic gestation is vast, and he who has not grasped it will fail to diagnosticate cases of ectopic pregnancy or will mistake them for something else. Tubal pregnancy, with normal genitalia, is an entirely different thing from an ectopic gestation occurring in a patient with a pathologic condition in the tube, the ovary and uterus. The symptoms of a tubal abortion are entirely different from those in a case of tubal rupture. In one case, the tubal abortion, the symptoms are not alarming, and the woman may recover, and the diagnosis may remain in doubt; while a case of tubal rupture, with an otherwise normal pelvic cavity, is so typical that no man can mistake it for anything else. Again, we have ectopic gestations which are strictly tubal and remain so from the beginning to the end, and they are the cases that are comparatively free from symptoms and go to the end of term with a living fetus, and they are easily removed because they are more or less pedunculated. No adhesions have taken place. In another case there may occur tubal rupture and the neighboring structures may become involved, and the fetus goes to the sixth or seventh month, when it dies for lack of nutrition and becomes encysted. In other cases the fetus undergoes solidification.

Dr. Hugo O. Pantzer, Indianapolis: I would like to add another symptom to the signs and symptoms given by Dr. Huggins which is invariably present, namely, a pulsating tumefaction on one side and not on the other. In rare instances it is attended with marked congestion or with tubal inflammation.

Dr. Charles L. Bonifield, Cincinnati: A great many women with ectopic gestation get well without operation. It is the experience of every operator, that after he has examined the specimen, he has wished he had left the patient alone.

Dr. William H. Wathen, Louisville: I have had approximately 150 of these cases, and of that number but one patient bled to death. That occurred about twenty years ago. I reached the patient just as a secondary hemorrhage had caused her death. These patients will not bleed to death if the rupture is between the folds of the broad ligament, and seldom or never if it is a tubal abortion. They may have a rupture through the tube into the peritoneal cavity. I believe that not one out of twenty-five women has died from secondary hemorrhage.

Dr. Walter B. Dorsett, St. Louis: A woman ran up to the third floor, fell, and died suddenly. A post-mortem examination disclosed the abdomen full of blood. She had bled to death from ruptured ectopic pregnancy. These women bleed to death more frequently than is stated by Dr. Wathen.

Dr. A. B. Miller, Syracuse: The general practitioner in many instances is not called sufficiently early to make a diagnosis. These patients feel perfectly well, but in six hours they become desperately ill, showing that rupture has taken place. We cannot always make an absolute diagnosis by the symptoms and physical findings.

Dr. D. C. Moriarty, Saratoga Springs: I believe it is well to operate early in these cases of ectopic pregnancy.

Dr. Miles F. Porter, Fort Wayne: It is not true that none of these women die of hemorrhage. I can find fifty men who operate on these patients practically as they come, and they will have a lower death-rate than another fifty men who practice the *finesse* referred to, and that is the reason I am not in favor of this extreme diagnostic *finesse*.

Dr. William H. Humiston, Cleveland: As a rule, these patients do not consult a physician unless they are very nervous and are in pain, and that is why a great many of the cases are not diagnosed before rupture.

Radiographic Diagnosis of Gastric and Duodenal Lesions

Dr. Lewis Gregory Cole, New York City: Anatomically and physiologically the first portion of the duodenum has always been considered a part of the small intestine, but normally it is dilated into a triangular cap which surmounts the pylorus and corresponds in size and shape with the stomach, and has absolutely no resemblance to the small intestine. Its motor phenomena correspond with those of gastric peristalsis, and it is absolutely free from the small, rapid, peristaltic contractions of the remaining portion of the duodenum. It is probable that the chyme in this portion has not yet been neutralized by the intestinal and pancreatic secretions. This may account for the fact that 90 per cent. of duodenal ulcers occur in this portion. I consider the pyloric sphincter as guarding the entrance to the intestine and allowing only that food that is recognized as properly prepared to be served to the intestine, and closing the door to prevent it from falling back into the stomach during diastole. The relative strength of the pyloric sphincter to the peristaltic contraction of the stomach is one of the most important factors in functional derangements of the gastro-intestinal tract. The diagnosis of gastric carcinoma at an early stage is now accomplished in a very large percentage of cases, and the radiologist is justified in either making a negative diagnosis or stating with certainty that there is either a benign or malignant lesion which requires an immediate operation.

Lipectomy for the Obese Abdominal Wall

Dr. Francis Reder, St. Louis: I have followed during abdominal operations the suggestion of Dr. Kelly to excise enough of the obese wall to facilitate intra-abdominal work, and in my experience in five cases the intra-abdominal work was rendered less difficult; but in two of the cases this fat caused considerable trouble, which was induced by a late section. It does not require any particular skill to cut away enough of the fat about the field of operation to get a sufficient amount of room for easier work; but it does require some knowledge to ablate these masses of fat that no untoward consequences may arise. To prevent any postoperative sequelæ, a wedge-shaped mass of fat should be removed, the two incisions converging into one on the fascial layer. This leaves no undetermined surface as a receptacle for secretions. It does not matter how long the incision is, provided there is no extensive undermining of the fat layer. I have found it of service to first carry the straight incision across the abdomen down to the fascia, this incision disclosing the thickness of the fat. By placing the left hand in the incision, and against the fat wall, I am able to guide more accurately the right hand in making the upper and lower flaps. After the ablation of the fat has been accomplished, the wound is covered with hot saline cloths, while the intra-abdominal work is being conducted. Fat removal is only to be recommended when the mass of fat is a distinct obstacle to the intra-abdominal work.

Personal Observations on Cancer

Dr. J. Garland Sherrill, Louisville: I have followed 208 patients and traced them to the present time. Of nineteen abdominal operations, eleven patients are living, five past the three-year limit, while others died in from twelve to eighteen months. Of twelve vaginal operations, four patients are living from three to twelve years after operations; eight had recurrence, dying within eighteen months. Trauma and irritation are important factors in the determination of the site of a malignant neoplasm. My cases show 8 per cent. in which trauma was noted, and 18 per cent. in which irritation was a factor. The results in my cases show very readily the improvement in ultimate results when radical surgical treatment is applied early. The serum treatment of cancer has been disappointing. I have used the ascitic fluid of one patient, which was injected into her own tissues, with no marked benefit, although the disease seemed not to progress during the time of its employment. Fulguration has not accomplished much, nor has the Röntgen ray done more than the knife or cautery can accomplish in a more thorough and certain way.

Sterilized Animal Membranes in Surgery

Dr. Robert T. Morris, New York City: For some years I have been experimenting with the absorbable-animal membranes in surgery, and have now and then found some point which seems to be new in this work. One case worthy of report was that of a young man, who, in riding down a steep hill on his bicycle, met an automobile coming up, turned aside suddenly into a bank, and the handle-bar of his bicycle tore five holes in the ileum. In that case there was so much contusion that I did not know where to resect. I washed out the blood and fecal matter, and decided temporarily to cover each opening with Cargile membrane until we might get past the period of shock, and then consider the possibility of excising bowel. The loops of perforated bowel were thrown about a small central drain and a large dressing applied, and the young man not only lived, but I did not do any excision of bowel. He was walking in thirty days without any fistula. That, I presume, was due to the use of the Cargile membrane and to nothing else.

Another point I have noticed with the Cargile membrane is that sometimes it does not undergo absorption rapidly. In an automobile accident, the patient having sustained a depressed fracture of the skull, I elevated the skull, separated the adhesions, and placed a large segment of Cargile membrane between the dura and the cranium. In this case there was occasion to do an operation some eight months subsequently for some remaining adhesions, and this membrane had not undergone any change whatsoever, so far as I could observe. It remained perfectly free and loose. It has prevented the formation of adhesions over the area I dressed and there were some supplemental adhesions about the periphery. This was an odd thing, and I do not know how to account for it. In many cases I have used the membrane for the prevention of recurrence of peritoneal adhesions as perhaps the favorite resource. In most cases now, in which I have occasion to separate extensive peritoneal adhesions, I depend on placing a sheet of this sterilized animal membrane over the area from which adhesions have been separated for the purpose of preventing a mechanical obstacle to the recurrence of adhesions.

Prevention of Shock

Dr. J. H. Carstens, Detroit: By simplicity and tact in management before the operation, much shock is prevented. Have everything ready in the operating room, and start the anesthetic immediately. Have all necessary ligatures and instruments at hand, so that there need be no delay during the operation. Analyze the case thoroughly beforehand, so that you may know exactly what you are going to do, and how you are going to do it, and what complications may arise. Give 2 quarts of a saline enema, or a hypodermic injection as soon as the operation is fininshed. Keep the patient free from pain for twenty-four hours after the operation.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Illinois: Coliseum Annex, Chicago, October 26-28. Sec., Dr. J. A. Egan, Springfield.

Louisiana: New Orleans, October 19-21. Sec., Dr. A. B. Brown, 108 Baronne Street.

New Jersey: The State Capitol, Trenton, October 17-18. Sec., Dr. H. G. Norton, 429 E. State Street.

West Virginia July Report

Dr. H. A. Barbee, secretary of the West Virginia State Board of Health, reports the written examination held at Charleston, July 10 to 12, 1911. The number of subjects examined in was 20; total number of questions asked, 120; percentage required to pass, 80. The total number of candidates examined was 70 of whom 59 passed, including 2 osteopaths and 11 failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Kentucky School of Medicine	(1897)	81
Louisville Medical College	(1904)	80
University of Louisville (1891) 80; (1911) 80, 81, 81, 83, 83, 83, 84, 84, 84, 85, 86.		
Baltimore Medical College (1907) 84; (1910) 85; (1911) 86, 89, 90		
College of Physicians and Surgeons, Baltimore (1910) 83; (1911) 81, 82, 83, 84, 86, 86, 88, 90, 90.		
Maryland Medical College (1903) 80; (1911) 80, 81, 81, 82, 84, 84, 84, 88.		
University of Maryland	(1911)	83
Ohio-Miami Medical College	(1911)	84
Cleveland-Pulte Medical College	(1911)	83
Eclectic Med. Coll., Cincinnati	(1910) 80; 1911)	80, 81, 82, 85
University of Pittsburg	(1910) 84; (1911)	85, 90, 92
Jefferson Medical College	(1911)	82, 83, 89

* Fell below 65 in one or more branches.

The following questions were asked, not including those in osteopathy:

ANATOMY AND EMBRYOLOGY

1. Name the bony prominences of the elbow and the ligaments of the elbow joint. 2. Give articulations of the first cervical vertebra. 3. Where is the spleen and what are its uses? 4. Describe the two principal arteries of the forearm and tell how they form the palmar arches. 5. Of what does a vertebra consist? Name the processes and tell what their object is. 6. Describe the stomach. 7. Give brief description of facial nerve. 8. Name the muscles of the shoulder and arm. 9. Name the sutures and fontanelles in fetal head. 10. Give difference in fetal and adult heart.

BACTERIOLOGY AND HYGIENE

1. Classify bacteria and give example of each. 2. Name the bacteria frequently found in soil, water, milk and air. 3. What are toxins and antitoxins? Give example of latter. 4. What is meant by phagocytosis? 5. Describe sterilization and antisepsis. 6. How would you prepare specimen (diphtheria) to be sent a laboratory for examination? 7. Describe pure water; how would you render it wholesome when contaminated? 8. Describe the location of well or spring in relation to privy vault or stable. 9. Describe the hygiene of a tuberculous patient. 10. Give causes of air contamination of school room and proper ventilation of same.

CHEMISTRY AND MEDICAL JURISPRUDENCE

1. Define chemistry. 2. How many elements are there? How represented? 3. Give symbols of gold, silver, iron, lead, arsenic, potassium, mercury, calcium and sodium. 4. Name elementary substances used in their pure state in medicine. 5. Define qualitative and quantitative analysis, with example of each. 6. What are mineral waters? Name three. 7. Define and illustrate an acid, base and salt. 8. What is a poison? Illustrate. 9. What are evidences of death by drowning? 10. Evidences of rape?

PHYSIOLOGY AND HISTOLOGY

1. Mention briefly chemical and physical changes in the air and the blood caused by respiration. 2. Discuss sleep theories, naming three hypotheses. 3. Discuss the origin, function and fate of the red-blood corpuscles. 4. State in percentage ratio of weight of blood to that of body. What percentage of loss may be borne? 5. Define systolic, diastolic and mean arterial pressure. How determined? 6. Define enzymes and discuss briefly their action. 7. Define protein, carbohydrate and fat. Estimate nutritive value. 8. What is bile? Discuss physiologic importance. 9. Describe histology of a transverse section of the spinal cord at the cervical enlargement. 10. Discuss the histologic structure of the blood.

PRACTICE OF MEDICINE AND PEDIATRICS

1. To what class of diseases does chorea belong? Give treatment and name important complications. 2. Give the prognosis and treatment in a case of aortic regurgitation with general arteriosclerosis 3. Give treatment of acute endocarditis. 4. Give causes, symptoms, physical diagnosis and treatment of acute croupous pneumonia. 5. Describe causes, tests, symptoms and treatment of typhoid fever. 6. Diagnosis and treatment of pleuritic effusion. 7. Diagnose, treat and give the cause of cholera infantum. 8. Write a prescription for modification of cow's milk for a child 3 months old. 9. What are the causes of convulsions in infants and children? 10. Give causes and treatment of summer diarrhea.

MATERIA MEDICA AND THERAPEUTICS

1. What is materia medica? What is pharmacy? 2. What is opium? Give its derivatives and dose of each. 3. Give composition of Dover's powder; Fowler's solution; Lugol's solution. 4. Give five principal emetics, dose of each and method of administering. 5. Name five intestinal antiseptics. 6. Give physiologic action of urotropin,† its dose and method of [illegible] is a specific in medicine? Give examples [illegible] application. 8. Define anesthesia; give examples of general and local anesthetics. 9. Define pyrexia and hyperpyrexia. How would you meet these conditions? 10. What are the therapeutic indications in intestinal hemorrhage in typhoid fever?

SURGERY

1. Give the methods of controlling hemorrhage. 2. Mention the uses of iodin in modern surgery. 3. Differentiate fracture of the surgical neck of humerus from fracture of anatomic neck of humerus. 4. Diagnose and treat carbuncle. 5. Give treatment of shock. 6. Give symptoms and treatment of cholelithiasis. 7. Diagnose and treat Colles' fracture. 8. Give symptoms and treatment of erysipelas. 9. Give symptoms and treatment of prostatic abscess. 10. Give symptoms and treatment of strangulated inguinal hernia.

SPECIAL PRACTICE

1. Give the symptoms of infantile spastic paralysis. 2. Differentiate between epileptic and hysteroid seizures. 3. Name the causes and dangers of otorrhea. 4. In what acute disease is the ear most commonly involved, and, as a rule, what part of the general structure of the ear is first attacked? 5. Name the conjunctival diseases due to microorganisms. 6. Name four causes of iritis, and note the subjective and objective symptoms. 7. In nephritis, where does the effusion of serum first appear? In cirrhosis of the liver, where? In cardiac diseases, where? 8. State the diagnostic value of a blood examination in chlorosis; appendicitis; trichinosis. 9. Give cause, symptoms, pathology and treatment for laryngismus stridulus. 10. Give symptoms and treatment for nasal polypi.

OBSTETRICS AND GYNECOLOGY

1. What is the placenta? From what is it formed? What is its structure and what are its functions? 2. Name the bones, straits and divisions of the obstetric pelvis. 3. What are the diameters of the pelvic outlet? How is it bounded? 4. Describe the fontanelles and their diagnostic uses. 5. What are the signs of pregnancy—probable, doubtful and certain? 6. Interstitial nephritis in a pregnant woman. How would you treat? 7. Name the diseases of the endometrium and state their effects in pregnancy. 8. Define miscarriage, abortion and premature labor. 9. Describe Crede's method for the delivery of the placenta. 10. What care does the mother require after labor? Define the nurse's duties.

MATERIA MEDICA AND THERAPEUTICS (HOMEOPATHIC)

1. What is materia medica? How are drugs prepared homeopathically? 2. Give the principal indications for aconite, arsenicum and veratrum alb., naming diseases in which they would be found. 3. What are the characteristics of cactus grandiflorus, phytolacca dec. and baptisia tinct.? 4. Name four drugs that have practically only a local effect and give their action. 5. Name four drugs that affect the organism generally and describe their effects. 6. Differentiate between phos. and hepar sulph. in diseases of the chest. 7. What are the indications for uranium nit. in nephritis? For arsen.? For merc. cor.? 8. Name three or four drugs that would probably be indicated in diseases of the testicles. 9. Name four drugs that particularly affect the mucous membranes; four that affect serous membranes. 10. What remedies are called for in melancholia? Give their indications.

PRACTICE OF MEDICINE AND PEDIATRICS (HOMEOPATHIC)

1. Name four of the most frequent complications of rheumatic fever. Give treatment. 2. What is multiple neuritis? Give clinical history, prognosis and treatment. 3. What would be your treatment for septicemia following a scratch on the hand? 4. What are the symptoms of cerebrospinal fever? Give treatment. 5. How would you manage and treat a case of diabetes mellitus? 6. Name the different types of malarial fever. Give treatment. 7. What are the symptoms of poliomyelitis? Give treatment. 8. What is icterus and what does it signify? 9. What is "summer complaint"? How would you treat it? 10. What is hemophilia? How would you treat it?

MATERIA MEDICA AND THERAPEUTICS (ECLECTIC)

1. Define materia medica, therapeutics Name five modes of administering drugs. 2. Give source, properties and therapy of ergot, hydrastis, strychnin. 3. Give physiologic action and specific symptomatology of apocynum, belladonna, digitalis, gelsemium. 4. What is the source of turpentine? Give its physiologic action, dose and therapy. 5. What is normal saline solution? How administered and in what conditions generally used? 6. Discuss therapeutic value of diaphoresis, diuresis, emesis and catharsis. 7. What drugs are available for local anesthesia? Give indications and technic of application. 8. Describe in detail therapeutic use of H_2O. 9. Name two gaseous disinfectants and give the technic of application. 10. What remedies would you use for the treatment of heat stroke, syncope, eclampsia and shock?

PRACTICE OF MEDICINE AND PEDIATRICS (ECLECTIC)

1. Name three clinical varieties of meningitis and give an etiologic factor in each. Diagnose and treat. 2. Diagnose and treat acute articular rheumatism. 3. Define Pott's disease. Give the etiology, diagnose and treat. 4. Give the symptomatology, diagnose and treat diabetes mellitus. 5. Give the etiology and diagnostic import of enlarged lymph-nodes. 6. Describe burns of the first, second and third degree and give treatment. 7. Diagnose and treat rachitis. 8. Give the etiology, diagnosis and treatment of ophthalmia neonatorum. 9. Differentiate measles and scarlatina. Diphtheria and follicular tonsillitis. Give treatment. 10. What is inflammation? Name the bacteria usually associated with ordinary inflammation and suppurative processes.

Wisconsin July Reciprocity Report

Dr. John M. Beffel, secretary of the Wisconsin State Board of Medical Examiners, reports that at the meeting held at Madison, July 11-13, 1911, 16 candidates were licensed through reciprocity, including 1 osteopath. The following colleges were represented:

College		Year Grad.	Reciprocity with
Rush Medical College	(1909)	(1910)	Illinois
College of Phys. and Surgs., Chicago	(1906)	(1910)	Illinois
Northwestern University Medical School	(1907)	(1910)	Illinois
Bennett Medical College		(1910)	Arkansas
Kentucky School of Medicine		(1901)	N. Dakota
Chicago College of Medicine and Surgery		(2, 1910)	Illinois
Baltimore Medical College		(1909)	Maryland
University of Michigan, Dept. of Med. and Surg.		(1903)	Michigan
Hahnemann Med. College and Hosp, Philadelphia		(1910)	Ohio
Western University, London, Ontario		(1899)	Nebraska
University of Naples, Italy		(1901)	New York

---

† Editor's Note: It is discouraging to note that those who examine and pass on the qualifications of physicians fail to appreciate their responsibilities. The graduates of the better schools know this product by its official name. It certainly will not raise the examiner in their estimation if he asks them about it under the name of one of the proprietary preparations of it. We suggest to this examiner that he consider the use of this additional query—not only for his candidates, but for himself: "What is the difference between urotropin, formin, uriform, aminoform, uritone and cystogen; and what is the difference between these preparations and the official hexamethylenamin?"

Book Notices

NOSTRUMS AND QUACKERY. Articles on the Nostrum Evil and Quackery from THE JOURNAL of the American Medical Association. Part I, Quackery. Part II, Nostrums. Part III, Miscellaneous. First Edition. Cloth. Price, $1. Pp. 509, with 220 illustrations. Chicago: American Medical Association Press.

In discussing the nostrum evil or quackery, the average physician is prone to assume that the layman is as well informed on the subject as he is himself. The physician does not realize that the public has not the same power of discrimination in these matters that he has. Medical schemes and assertions, which to the profession are transparent and evident frauds, may, to the man in the street, seem plausible and reputable. It is only when his patients come to him for information regarding the efficacy of certain widely advertised "patent medicines" or the possible value of some quack's exploited "treatment" that the physician realizes the deep and abiding ignorance of the public on all things medical. At such times, too, he is made to realize his own lack of specific information on such subjects. By every such physician the book "Nostrums and Quackery" will be appreciated; to the layman it will be of great value. No man unfamiliar with the detailed methods by which the quack captures his prey can read this book without being impressed with the hollowness of the fraud on which all irregular practice is based. The same may be said of the related subject of nostrum exploitation. By scores of examples, it is shown that "patent medicines," far from possessing some peculiar potency not to be found in the prescriptions of physicians, are either cheap imitations of such prescriptions or absolutely worthless—and sometimes dangerous—mixtures without any therapeutic virtue. This book differs from similar works in the thoroughness of detail with which each subject is treated. Step by step the methods of the quack are described in detail. Samples of form letters are given, testimonials are traced down and shown to be worthless or fraudulent, the remedies themselves analyzed—in fact, the book practically tears aside the veil of secrecy that has hitherto concealed the innermost workings of quackery. Every intelligent layman who reads this volume will have a better understanding of the limitations and possibilities of reputable medicine and he will be better able to conserve both his own health and the health of those dependent on him. The book is free from technical terms, is written in popular style and, with its two hundred odd illustrations, must appeal to all who have an interest in the subjects which go to form its title.

PATHOLOGY AND BACTERIOLOGY [OF THE EYE]. By E. Treacher Collins, F.R.C.S., Surgeon to the Royal London Ophthalmic Hospital, and M. Stephen Mayou, F.R.C.S., Surgeon and Pathologist to the Central London Ophthalmic Hospital. An International System of Ophthalmic Practice. Edited by Walter L. Pyle, A.M., M.D., Philadelphia, Member of the American Ophthalmological Society. Cloth. Price, $4 net. Pp. 558, with 237 illustrations. Philadelphia: P. Blakiston's Son & Co., 1911.

The senior writer of this admirable manual has undoubtedly taken for his text a sentence from his own "Erasmus Wilson Lectures on the Anatomy and Pathology of the Eye" the statement that "there is a law in biology to the effect that various stages of development through which the individual passes typify the history of the race"; since a perusal of the book furnishes evidence that the authors regard pathologic processes mainly in their evolutionary and embryologic aspect—a point of view which is not only original but eminently scientific.

The chapter on "Aberrations in Development" is an interesting one and deserves particular attention. It will, however, be possible to refer to only a few instances of the abnormalities mentioned in it. The authors mention the fact that in various animals the blood-supply of the retina varies considerably. In some mammals the retina is devoid of blood-vessels; in others they arise directly from the ciliary system in the sclerotic and reach the retina at the disk margin around which they curl; in still others the supply is mixed, some from the ciliary vessels and others from the central retinal system. This anatomic statement forms a preface to the consideration of the abnormal conditions found in man, the writer pointing out in this connection that many pathologic changes, including arrest of development, often simulate anatomic conditions that are normal in the lower animals.

We rather expected that definite mention would have been made of the dotted opacities found and described by Mittendorf as occurring in the posterior lens capsule and believed by him to be the remains of the (intra-uterine) attachment of the hyaloid artery. The occasional occurrence of an opacity of the posterior surface of the lens is mentioned, but this is evidently not the phenomenon spoken of by the American writer.

The anomaly of the papilla known as "pseudoneuritis" is described and the case of Holmes Spicer quoted. The pathology of the various extra- and intra-ocular neoplasms is extensively considered and their relation to evolutionary remains and embryologic tissues minutely described. Neuro-epithelioma of the retina (glioma) is judiciously considered. The "rosette-like" formations are regarded as rudimentary rods and cones. In this work an explanation is given not only of the ordinary morbid processes that affect the eye, but the tissue changes in many rare cases are duly delineated. We have particularly in mind the development of cysts in detached retina (p. 170), the pages and cuts illustrating the eye of Cyclops and some of the illustrations in the section on increased intra-ocular tension.

Reports in this text-book on the histologic and bacteriologic state of eyes lost after operations are of extreme value to the surgeon who is in the habit of doing much operative work. He will find the pages describing the post-mortem appearances in these cases of great interest, explaining as they do the failure of certain surgical interventions, and forewarning him in a vivid way of dangers to be avoided and technical errors to be corrected. The authors evidently attempt, and often succeed, in telling us just why "things go wrong" as well as how they might have gone right.

The investigations of Collins and Mayou do not permit them to answer the question as to whether "concussion" cataract is or is not sometimes produced without actual rupture of the lens capsules. Some authorities believe that this lesion may occur with an intact capsule, as the result of a mechanical tissue alteration whose interference with the nutrition of the lens fibers brings about the lenticular clouding.

Chapter V ably deals with the subject of inflammation and its modifications as seen in the ocular structures. The chapter on "Parasitic Diseases of the Eye" very properly includes the bacteriology of that organ and here, we need not say, there is little left to be desired. The subject is fully covered with a precise brevity that is in striking contrast to the learned verbosity of some other foreign monographs we might mention. In an appendix are given various practical methods for making post-mortem examinations of the eye, such as cutting, staining and mounting microscopic specimens, and the book ends with a concise description of the Wassermann reaction, the preparation of vaccines and the agglutination test.

A PRACTICAL MEDICAL DICTIONARY of Words Used in Medicine, with Their Derivation and Pronunciation, Including Dental, Veterinary, Chemical, Botanic, Electric, Life Insurance and Other Special Terms; Anatomic Tables of the Titles in General Use and Those Sanctioned by the Basel Anatomic Convention; Pharmaceutical Preparations, Official in the U. S. and British Pharmacopeias and Contained in the National Formulary; Chemical and Therapeutic Information as to Mineral Springs of America and Europe, and Comprehensive Lists and Synonyms. By T. L. Stedman, A.M., M.D., Editor of "Twentieth Century Practice of Medicine" and the *Medical Record*. Leather. Price, $5. Pp. 1,000. New York: William Wood & Co., 1911.

This book presents a number of novel features. Attempt is made to use the etymologically correct terms, for instance, "oothecectomy" instead of "oophorectomy," "scolecoiditis" for "appendicitis," etc. This is in line with similar attempts made elsewhere. Derivations are given from the Anglo-Saxon as well as from Latin and Greek. Special attention is also paid to synonyms and to listing under the name of a part the scientific terms for various conditions associated with that part. Thus under "abdomen" are found the various terms for abdominal dropsy, examination, incision, pain, tumor, etc. Under "pain" are listed pains which may be felt in any part of the body. Under "uterus" are listed the various anomalies of development as well as the pathologic conditions to be met with in this organ. This is extremely useful to one who is at a loss for the proper word to be used as well as to secure a correct definition. The usual tables of arteries, muscles, nerves, etc., found in a dictionary, are contained in this volume. Eponymic terms are inserted as main titles and are defined under the proper name; a short biographical sketch is added in each case. The reduction in the number of hyphenated words will commend itself to many. The Basel nomenclature is followed throughout. All the preparations of the United States and the British Pharmacopeias and the National Formulary are included. Mineral springs are listed as well as their location, character of the water and indications for its use. Besides the regular medical terms, the dictionary includes dental, chemical, veterinary, botanical insurance, homeopathic and eclectic terms. Tables of elements, their symbols and atomic weights, thermometer scales, weights and measures, etc., are placed in the appendix. Special attention is paid to the etymology of words, and in the spelling of medical terms preference is given to the simpler forms. In words derived from the Greek the kappa is represented by the English "c." While this looks all right so far as "catalepsy" is concerned, it has a rather strange look in the word "caryocinesia." Daily use of the book has brought to light many good features, but every now and then a word or term is missed in it for which some other dictionary is consulted successfully. This, of course, is to be expected, as an absolutely complete dictionary, not encyclopedic in character, is out of the question. What one author will regard as an important word another will not consider as worthy of inclusion. On the whole, however, the author seems to have been judicious in his exclusions and the book therefore takes a high position as a reference "word-book" in medicine.

AMERICAN PRACTICE OF SURGERY. A Complete System of the Science and Art of Surgery. By Representative Surgeons of the United States and Canada. Editors: Joseph D. Bryant, M.D., LL.D., and Albert H. Buck, M.D., of New York City. Complete in Eight Volumes. Volume VIII. Cloth. Price, $7. Pp. 1146, with 406 illustrations. New York: William Wood & Co., 1911.

The eighth and last volume of this work will be welcomed by all who have been fortunate enough to have subscribed to it. In this volume are considered intrathoracic surgery, surgery of the spleen, surgical diseases and wounds of the kidneys and ureters, surgery of the pancreas, surgery of the liver, gall-bladder and biliary passages, surgical diseases, wounds and malformations of the urinary bladder and the prostate and surgery of the ovaries and Fallopian tube and the uterus, including extra-uterine pregnancy, Cesarean section, etc. The chapter on carcinoma of the uterus is particularly worthy of notice.

The work has been favorably commented on repeatedly in these columns as the various volumes appeared. This last volume is particularly noteworthy in that several subjects of interest to the surgeon are considered which heretofore have not been found incorporated in works of this kind. Of these we may mention an excellent chapter on "The Law in Its Relations to the Practice of Surgery" and one on "Administrative Surgical Work" which has subheads on hospitals and hospital management, military surgery, naval surgery and administrative railroad surgery. Closing the volume and work is an extensive index to all the volumes. The work as a whole reflects great credit on the individual authors, who usually receive but little of any recognition in composite works of this character. At the same time the editors are to be congratulated on having brought to a successful termination such an excellent exposition of the practice of modern surgery.

THIRD ANNUAL REPORT OF THE MICHIGAN ASSOCIATION FOR THE PREVENTION AND RELIEF OF TUBERCULOSIS. For Ten Months, March 1-Dec. 31, 1910. Containing Statement of Work Accomplished, Report of Convention at Ann Arbor, Report of Local Associations, State Needs, Work of Allied Societies, Report of Secretary and Treasurer. A Brief of the Ten Months' Work. Aldred S. Warthin, Secretary, Ann Arbor, Mich. Paper. Pp. 189.

This organization has adopted as its war cry: "No Tuberculosis in Michigan in 1920." This report reviews the work for 1910, and contains much interesting material and many illustrations. The reports on the publicity and educational methods used are particularly interesting.

What Constitutes Vaccination and Form of Certificate Thereof that May be Required

(Lee vs. Marsh (Pa.), 79 Atl. R. 564)

The Supreme Court of Pennsylvania holds that the vaccination of school children required by the statute of that state is by inoculation, and that a form of certificate may be demanded showing that the certified vaccination of a child was by that method. The certificate of vaccination offered in this case stated that the physician signing it, after personal examination of the child named therein, certified that she had been successfully vaccinated. The form insisted on, under instructions from the department of health, was to the effect that on a certain date the physician vaccinated the child named, and on another date stated found a resulting sore, which in his opinion meant a successful vaccination. The vaccination in this case was by the giving of vaccine virus (triturated virus) through the alimentary canal, through the mouth, in a powder form.

The Supreme Court renders its decision on the opinion of the court below, which stated that the whole case really turned on what is the meaning of the term "vaccination," as used in the act of June 18, 1895, which prohibits the attendance of a child at school without a certificate of successful vaccination, or of its having had the small-pox.

The ordinary and usual meaning of "vaccination," and the sense in which it must be supposed to have been used by the legislature, is inoculation with the virus of cow-pox for the purpose of communicating that disease as a prophylactic against small-pox. It indicates an operation, and not a result. If a person should take cow-pox by milking cows, or otherwise, or from other contact with the disease, he could not be said to have been vaccinated. The operation is comparatively old, having been in use for over 100 years, and during that time has always consisted of inoculating the body—that is, grafting on it the disease by inserting the virus under the skin—and the test of its success has always been considered to be the appearance of the symptoms of the disease, including those which manifest themselves on the skin.

Still it appeared in this case that for some years past another method of guarding against small-pox has been in use, more or less extensively, which consists in attenuating to a high degree the virus of small-pox, or of cow-pox, the attenuation of the virus of small-pox being called variolinum, and that of cow-pox vaccininium, and administering one or the other of these substances by the mouth, and it was claimed that in this way there are produced in the body practically the same symptoms as are produced by vaccination, except the exterior and local inflammation, and that either of these methods has the same preventive virtue as ordinary vaccination. From what is known of the use of toxins of other diseases, this would seem to be possibly true; but whatever it may be, and whatever the result may be, it is not vaccination as the term is used in the act.

The term "vaccination," however, appears to be used by some physicians, at least, as a general term for the introduction into the body, by any method, of any kind of virus as a preventive of disease, and it is plain that in this case the physician who certified to the successful vaccination used the term in this general sense, and not in the sense of the act. In order, therefore, to guard against such ambiguous use of the term by which the act would be evaded, the health department, under the terms of the act of April 27, 1905, prescribed a form of certificate which would prevent such ambiguity, and the requiring of that form was really what is complained of in this case. It was strenuously argued that the authority given by the act of 1905 to the health department to fix forms of certificates is a delegation of legislative power, and if it were claimed to authorize that board to require safeguards against disease which the act does not substantially require, it would be open to that objection. But all the court understands the act of 1905 authorizes, and all that the department has done in this case, is to regulate the form of the certificate so as to prevent ambiguity, and to require the certifying physician to use words in the same sense with which they are used in the act.

For these reasons the court is of the opinion that the certificate required by the board of health was lawfully required by it, and that its use is obligatory.

May Testify in Will Cases as to Mental Condition

(In re Gray's Estate (Neb.), 130 N. W. R. 746.)

The Supreme Court of Nebraska holds that, in a contest over the probate of a will between the person therein named as an executor or a legatee and the heirs at law of the decedent, section 333 of the Code of Civil Procedure, forbidding the disclosure of privileged communications, does not prevent a physician from testifying on behalf of either side of the controversy to the mental condition of the testatrix, though the information which enables him to do so was acquired solely in his professional capacity while attending her during her last illness. The court says that the courts of the country are divided on this question, but this court has held that the statutory right of waiver extends to the personal representative of a deceased person. Then, may one class of representatives in a contest over the probate of a will waive the privilege to the exclusion of another class, where the respective rights of the disputants depend on the mental condition of a deceased person? Does the statute permit heirs at law to require a disclosure on part of the physician, if his patient was insane, and suppress the truth, if mentally competent? No such intention can be found in the statute or in the reasons for its enactment. If heirs at law to protect the property of their ancestor from an insane act and to obtain their own rights under the statute of distributions may require a physician to testify to the condition of his patient's mind, there is no reason why a legatee or an executor may not also call on him for the purpose of protecting the will and a legacy under it. Having held that the right to waive the statutory privilege extends to the personal representative of a deceased person, consistency and justice require a construction which permits an executor or a legatee to compel a physician to testify to the mental condition of his patient, when that question is involved in a contest with the heirs over the probate of the patient's will. The courts, however, have authority to protect the memory of deceased persons from objectionable disclosures.

County Societies Can Pass Certain By-Laws and Hold Members for Trial on Charges—Not Subject to Injunction

(Ewald vs. Medical Society of New York County, 128 N. Y., S. 886)

The First Appellate Division of the Supreme Court of New York holds that a member of a medical society is not entitled to an injunction to prevent his being tried on charges preferred against him where his resignation has not been accepted and the by-laws of the society provide that all resignations shall be in writing and shall be sent to the secretary and referred to the comitia minora at its first meeting after their receipt, and, if accepted, the member thereby severs all connection with the society, but no resignation shall be accepted from a member under charges.

The court says that, if he is still a member of the society, his suit for an injunction is premature, while it also may well be doubted whether equity will entertain jurisdiction at the suit of a non-member to restrain the proceedings of a membership corporation like the defendant society. But he may ignore the proceeding, and, if he is libelled, sue for damages.

Under the laws applicable thereto, the society not only had the power to expel for unprofessional conduct not directly involving the relations of the member as such to the society, but it also had the power to pass the by-law that no member should be permitted to resign under charges. Indeed, its relation to the public and to the profession is such that the mere severing of membership of one guilty of an offense meriting discipline would not serve its corporate purposes. County medical societies are much more than mere private corporations or social clubs. The scope of the original act of incorporation and of the subsequent acts relating to them shows that they were intended to discharge important duties to the public.

It seems plain, therefore, that a member on his admission to the society assumes an obligation, not only to conform to the rules and regulations of the society respecting his immediate relations to it, but as well to observe its standards of professional ethics, and that a breach of that obligation in any respect involves a violation of duty to the society. Certainly any discreditable act of a member in his professional relations tends to discredit the society. The plaintiff agreed on becoming a member to submit to the discipline of the society for any act unfavorably affecting "the character, dignity or interest of the medical profession, or of the society." The by-laws, rules and regulations of the society would have no sanction if its discipline could be evaded by a resignation.

It is probable that the defendant could not try a member while under suspension. But it could wait until the period of suspension expired, or it could revoke the suspension. Restoration is not the same as original admission to membership. After restoration, he probably could not again be tried on the charges on which he was suspended. But that would not affect charges entirely different.

A Communication Not Privileged

(Miller vs. Miller (Ind. App.), 94 N. E. R. 243)

The Appellate Court of Indiana, Division No. 1, holds that in this case, wherein a daughter sought to recover from the estate of her deceased mother for services rendered her mother before her death, that there was no error in permitting a witness who was a physician to testify that while at the home of the mother, on an occasion when professionally calling on her, she said to him, in the presence of the claimant, "that Ellen should be paid and well paid for the work she was doing there caring for her." The court says that the mother was at that time able to be up and around, and this conversation occurred in the sitting-room of her home. The objection urged against the admission of this evidence was that the communication was privileged, being a communication from a patient to her physician. But it did not appear that the statement to the witness was in any manner connected with the making of any examination of the patient, or in connection with any conversation with reference to her ailments or disease with which the patient was suffering or being treated, or in any manner pertaining to such physician's employment, or while any one was advising the claimant as to the care and attention the mother should receive. All persons are competent witnesses in a civil proceeding except as otherwise provided by statute. The Indiana statute provides that: "Physicians, as to matter communicated to them, as such, by patients, in the course of their professional business, or advice given in such cases," are not competent witnesses. Such matters are regarded as confidential communications between patient and physician, and are privileged without the consent of the patient. The fact about which the witness testified here was not a matter reasonably within the professional business of the physician, or about which he would be expected to give advice, or that it would likely be communicated by a patient to a physician as such, and was not privileged.

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

Philippine Journal of Science, Manila

June, VI, No. 3, pp. 165-258

1 Davainea Madagascariensis (Davaine) in Philippine Islands. P. E. Garrison, U. S. N.
2 Influence of Rice Diet and Inanition on Production of Multiple Neuritis of Fowls and Its Bearing on Etiology of Beriberi. W. P. Chamberlain, H. D. Bloombergh and E. D. Kilbourne, U. S. A.
3 Intestinal Parasites in Cavite Province. E. R. Stitt, U. S. N.
4 *Dysentery Bacillus with Bacteriologic Study of Epidemic of Bacillary Dysentery in Philippines. E. R. Whitmore, U. S. A.
5 Practical Experiences with Beriberi and Unpolished Rice in Philippines. V. G. Heiser, U. S. P. H. and M.-H. S.
6 Perineal Litholapaxy (Keith's Operation). A. Hooton, Rajkot, India.
7 *Clinical Study of Hookworm Infection in Philippines. L. Gomez, Manila.
8 *Etiology of Beriberi. W. P. Chamberlain and E. B. Vedder, U. S. A.

6. **Dysentery Bacillus.**—During an epidemic of bacillary dysentery in the Philippines, occurring in the summer of 1909, Whitmore was able to isolate dysentery and dysentery-like bacilli from the stools of a number of patients. He isolated a bacillus of the Shiga-Kruse type from twelve out of forty cases of severe, acute dysentery in natives of two towns of Batangas Province where there was an epidemic of acute dysentery with a high mortality. No other strain of the dysentery bacillus was found by him in that locality. He was able four times to isolate a bacillus of the Flexner-Strong type, and one of the Shiga-Kruse type once from sporadic cases of acute dysentery around Manila. Beside this, he obtained a large number of dysentery-like bacilli. These organisms were determined by the cultural characteristics, including their reactions in sugar media, their pathogenicity for lower animals, and their agglutination reactions with sera of animals immunized to known strains of the various types of the dysentery bacillus. The bacillus Y and the Strong type, with which Lentz worked, were not found. Whitmore says that great care is necessary in describing types of the dysentery bacillus from their reactions in sugar media alone, as the amount of sugar present and the length of time the organism has been on artificial media often affect the reaction.

7. **Uncinariasis in Philippines.**—This investigation was undertaken by Gomez mainly to determine the effect of the hookworm on Filipinos, and to determine whether there is any immunity enjoyed by the race comparable to that of the Negroes in Porto Rico, in the southern United States and in Africa. A series of twenty-six cases was studied clinically, and subjected to a careful examination of the blood and urine. In a few cases the hookworms were collected and counted. It has been Gomez' procedure to collect the stools in every case. Ten cases without hookworms but with other intestinal parasites were selected for study as controls.

Five of the twenty-six patients complained of a certain amount of pain in the stomach. The other symptoms, such as emaciation, a feeling of dizziness, pain in the joints, difficulty in urination, a sensation of oppression on the chest, tympanitis, neuralgic intercostal pains, or debility, can be attributed to other diseases such as malaria, tuberculosis, dengue fever, cystitis and nephritis. The vague pains in the stomach suggest the presence of hookworms, either alone or associated with other intestinal parasites, as their removal accompanying hookworm infection has been frequently observed by Rissler and Gomez. One particular instance was that of an assistant who complained of poor appetite and vague abdominal pains, and who was promptly relieved on the expulsion of hookworms. As compared with the control cases, eosinophilia is generally present in the patients harboring hookworms. Five out of ten, or 50 per cent., of the control cases gave an eosinophil count above 4 per cent. In patients infected with hookworm, twenty out of twenty-six, or 76 per cent., had eosinophils above 4 per cent. Only three of the controls had over 5 per cent., whereas in the hookworm series this figure was reached by twenty out of twenty-six of the cases. No control shows 13 per cent. or above, whereas nine (or 34 per cent.) of the patients harboring hookworms gave an eosinophil count of 13 per cent. or above. The lowest count in the control cases was 0.3 per cent., and the highest 12.80, whereas in the others the lowest was 0.3 per cent. and the highest 21.9. It was noted in the control series that individuals with *trichuris* or *ascaris*, or both together, hardly show any deviation from normal, those having high eosinophil counts harbored amebas or *tenia*. The percentage of hemoglobin in the control series varied from 80 to 95. In these patients infected with hookworm, the percentage was from 75 to 95.

The count of the red and white cells did not show any marked difference between the two series; the lowest for red cells in the hookworm cases was 4,000,000 per cubic centimeter, whereas in the control cases it was 4,500,000. In two instances, albumin was found in the urine but this occurrence can be attributed to nephritis which was independent of the hookworm infection. The number of hookworms recovered varied from one to twenty, this small number corresponding to the paucity of eggs found in the microscopic preparations. Gomez concludes that hookworm infection among the Filipinos corresponds to the light type of Stiles; that is, patients have the ova of hookworms in their stools, but no symptoms. The absence of all clinical manifestations or their insignificant characters among Filipinos infected with hookworms, Gomez says, cannot be attributed to a racial immunity, as the number of the infecting hookworm organisms in each instance is small.

8. **Etiology of Beriberi.**—A series of carefully conducted experiments on fowls has convinced Chamberlain and Vedder that polyneuritis gallinarum is not prevented by adding to a diet of polished rice any of the following substances: potassium phosphate, potassium citrate, potassium carbonate, potassium chlorid, magnesium phosphate, phosphoric acid, or phosphoric acid combined with potassium chlorid. The neuritis-preventing substance in rice polishings is soluble in cold water and in cold alcohol. Polyneuritis gallinarum may be prevented by means of an extract of rice polishings containing only those substances soluble in cold water and cold alcohol. Multiple neuritis in fowls fed on polished rice probably is not due to lack of phosphorus compounds in the grain, as claimed by Schaumann, since out of each 1,000 parts of phosphorus contained in the rice polishings at least 999 are not concerned in preventing neuritis. The neuritis-preventing substance contained in rice polishings is capable of dialysis through a parchment membrane. This excludes all colloids from consideration.

15 *Treatment of Puerperal Sepsis by Intravenous Injection of Mercuric Bichlorid. H. M. Stowe, Chicago.
16 Asiatic Cholera and Its Treatment. W. F. Waugh, Chicago.

15. **Treatment of Puerperal Sepsis.**—Stowe reports eleven cases of undoubted septicemia treated during the past four years by the intravenous injection of mercuric bichlorid in association with other treatment, with death following in five and recovery in six. In addition to these eleven cases of septicemia the mercury has been injected in three cases of pyemia. One woman died after seventy days. Of the other two patients one was treated with 2 grains of mercury after the ninth chill, the other with 1 2/5 grains after seven chills. Four additional chills followed the treatment, making eleven in all. In the first case, the blood was sterile after five examinations; in the second case streptococci were demonstrated in the blood-current. Stowe has given 185 injections of 1/5 grain of mercuric bichlorid in septic patients and has never seen any bad or toxic results therefrom. He says that intravenous medication offers the quickest, most accurate and most dependable method of drug administration. The reputed dangers of embolism are greatly over-estimated. Mercuric bichlorid is not the ideal drug to combat septicemia, but it has the advantages of being easily associated with other forms of treatment, is harmless in action and is worthy of trial in serious cases. Stowe warns to keep the teeth clean and to omit salines during the course of treatment. He emphasizes that experiments with other chemicals in the conflict against the streptococcus are greatly needed. By diligent investigation someone will find a substance which will overcome the streptococcus and its toxins and also prove harmless to the maternal organism.

Stowe says that generally speaking, local forms of sepsis are treated on the principle of watchful expectancy because the maternal powers are amply able to overcome the deleterious action of the bacteria and their toxins. No intra-uterine or vaginal douches are given, no curettement permitted and no internal examinations made; in fact, local therapy consisting of vaginal or uterine manipulations is not only useless, but are positively harmful in the great majority of cases. Many a woman owes a general extension of her sepsis to malicious local therapy. It is only necessary to assist the maternal powers in their conflict against the streptococcus, the most common as well as the most serious pathogenic organism. This assistance is afforded by placing the patient in Fowler's position to facilitate drainage, ergot and hydrastis to prevent extrauterine migration of the bacteria and to promote an otherwise retarded uterine involution, and continuous ice-bags on the abdomen for the relief of pelvic pain. In cases of parametritis, when exudation is pronounced, the patient is kept in bed for several days after the pain, temperature and other signs of the acute process have subsided. If fever or pain return after the woman leaves her bed, she must return at once; otherwise, the exudate may suppurate and form a pelvic abscess. These abscesses should not be opened until they are easily accessible by way of Douglas' cul-de-sac, never through the abdomen, and when the peritoneal cavity is sufficiently protected by adhesions from the suppurating focus. A premature surgical procedure is always associated with the danger of general peritoneal involvement.

22 *Surgical Treatment of Exophthalmic Goiter. W. Bartlett, St. Louis.

22. **Surgical Treatment of Exophthalmic Goiter.**—Of Bartlett's operations for this disease, forty-five were partial thyroidectomies. Two of these patients died (4.44 per cent.); thirty-two (71 per cent.) are in splendid condition at periods varying from a few weeks to seven years after the operation. Bartlett does not advise thyroidectomy on advanced patients unless a preliminary hospital treatment, consisting of rest in bed, atropin and the application of ice to heart and throat alters the condition to the point that he considers them fair surgical risks. If they are properly chosen, an anesthetic is dispensed with, no blood is lost and no shock produced; surely very little is added to the inherent danger of the disease and in this way a vast amount is accomplished. Bartlett operates under local anesthesia.

24. **Spurious Pregnancy.**—In Clifford's case the woman's menstruation ceased Aug. 10, 1908. She believed that she had conceived and had no disagreeable symptoms. The abdomen enlarged progressively, and the patient stated that she felt movements about Christmas. Early in February she complained of the activity of these movements, and for the first time grew nervous and worried over the tediousness of her state. Clifford saw her Feb. 4, 1909, and with the exception of a marked anemia, found the patient in good condition. A symmetrical tumor at the level of the umbilicus was palpated, but the fundus of the uterus was not determined, nor were the fetal heart sounds and other positive signs of pregnancy present. On February 23 permission to administer an anesthetic was given, and as soon as consciousness was lost the tumor disappeared and a slightly enlarged uterus, with a soft patulous cervix was palpated. With the withdrawal of the anesthetic the swelling returned, and the symptoms enumerated above reappeared. The patient insisted that she still felt fetal movements that annoyed her greatly, and her nervousness became so marked that it was decided to perform a curettement. This was done March 10, 1909, and only some catarrhal endometrium was found in the scrapings. Satisfied now that the uterus was empty, the patient did not complain and the abdomen remained normal, the anemia present readily responded to treatment and the nervousness cleared up gradually. Menstruation returned June, 1909, and continued regular until November, 1909. Jan. 9, 1910, a two-months' pregnancy was terminated unavoidably caused by a fall on an icy side-walk. Placental debris was found in the discharge at this time; menstruation did not again appear, and on Nov. 22, 1910, Clifford delivered this woman of a normal female baby.

37 Case of Alkaptonuria and Ochronosis. P. M. Ashburn, U. S. A.

35. **Epidemic of Measles.**—Since the 24th of last December there have been 183 cases of measles at Columbus Barracks. During the first month and a half the disease ran a very mild course, with few complications and those not serious. Up to February 16 there were seventy-six cases of measles, two of them being complicated with bronchopneumonia, three with otitis media, and one with plastic pleurisy; none of these cases was severe and all of them made good recoveries. About the middle of February the disease suddenly assumed a serious aspect and many of the cases had severe complications. There seems to be no way to explain this sudden change in the character of the disease. The patients were isolated in roomy wards, well ventilated but kept at an even temperature, and with sufficient moisture present. That there was an increase in the virulence of the infection is indicated by the fact that during this latter part of the epidemic many cases were seen to be serious from the start. Even during the catarrhal stage there was great prostration, very serious bronchitis, and early tendency to lung involvement. The first death occurred on Feb. 16, and since that time there have occurred 107 cases of the disease with a total of sixteen deaths. The last death occurred on April 1, and since that time there have been only a few cases and none of them serious. The death-rate for the entire epidemic is 8.2 per cent.

The following complications occurred during this epidemic: bronchopneumonia, 23; pleurisy with effusion, 11; otitis media, 13; mastoiditis, 3; meningitis, 1; pericarditis with effusion, 3; abscess of lungs, 2; 1 with appendicitis as an intercurrent disease, was operated on and made a good recovery. At autopsy one patient was found to have a large tuberculous abscess in the apex of each lung, and two had healed tuberculous nodules.

Death was caused in four cases by bronchopneumonia alone; in one case by meningitis; in four cases by bronchopneumonia and pleurisy with effusion; in one case by empyema, which proved fatal in spite of rib resection and thorough drainage; two cases with bronchopneumonia and multiple abscesses in the lungs; one case with bronchopneumonia and tuberculous abscesses; and two cases with bronchopneumonia, pleurisy with effusion, and pericarditis with effusion.

Otitis media was a complication in 7 1 per cent. of the cases. In those cases in which the discharge was at all persistent, an autogenous vaccine was made and proved a very efficient aid to the treatment. Mastoid disease was a complication in three cases; in all three a thorough mastoid operation was done; two of the patients recovered and the other died with meningitis.

58 Case of Urinary Suppression Treated by Catheterization of Kidney Pelvis. F. C. Walsh, San Antonio, Texas.

53. **Renal Decapsulation in Eclampsia.**—Ehrenfest draws from his experiments the following conclusions: 1. The immediate effect of decapsulation is a temporary suppression of secretory function in the operated kidney, and a distinct reflectory retardation of diuresis also in the other kidney, at time probably amounting to a complete anuria. This reflectory effect is also exerted on a kidney decapsulated forty-eight hours previously, but possibly to a smaller degree. 2. From twenty-four to forty-eight hours after the operation a decapsulated kidney shows approximately the same secretory activity as the non-decapsulated kidney of the same animal. 3. Between twenty-four and forty-eight hours after decapsulation the diuretic effect of an intravenous saline transfusion or of an artificial acute rise of blood-pressure is identical in the decapsulated and non-decapsulated kidney [illegible] the same animal. 4. In an apparently healthy dog a kidney, decapsulated for more than twenty-four hours, does not show any noticeable difference from the other kidney in regard to its secretory function under normal or artificial conditions.

54. **Renal Anomalies.**—The two cases reported by Dorland are: 1. Mural kidney, situated in a pocket of peritoneum on the anterior abdominal wall, left lower quadrant. The organ was one-third of the normal size, having a small ureter which perforated the bladder-wall in the usual situation, so that the normal shape of the vesical trigone was not altered. The ectopic kidney was normal in shape, but showed slight lobulations, the latter not being nearly so marked, however, as they frequently are in normally situated and fully developed kidneys. A careful dissection proved that the vascular supply of the ectopic organ was derived from a branch of the internal iliac artery, with a corresponding vein emptying into the internal iliac vein. The adrenal was not in evidence. The ureter, which in common with the vessels perforated the kidney at the hilum, which was directed inward and downward toward the median line, was about half the usual size. Section of the ectopic organ discovered typical renal tissue, although the pyramids were not as sharply defined as in a normal kidney. There was no kidney nor adrenal body in the normal situation on the left side, nor were ureter or renal vessel to be found on that side, nor vestiges that might indicate an attempt at renal formation. The right kidney, adrenal body, and ureter were normal in size and appearance and were normally vascularized. The second case was one of horseshoe kidney with fusion of the upper extremities with concavity directed anteriorly.

55. **The Sigmoid and Pelvic Disease.**—Barrett emphasizes that the intimate relation of the genital tract to the terminal reservoirs of the urinary and alimentary tracts permit of easy communication of disturbances and pathologic conditions. The sigmoid through its ready adhesions may, like the omentum, serve to wall in a genital infection and save the patient, after which it may, through perforation, serve as a means of escape for this infection and the resulting pus, or, by reason of adhesions, it may introduce new elements of danger through colon bacilli infection and bowel obstruction. The symptoms of constipation, diarrhea, passage of mucus or blood, the presence of a sausage-like mass in the left iliac fossa, etc., should, he says, lead us more frequently to include the pathologic conditions of the sigmoid in our pelvic diagnosis, especially when there seem to be adhesions on the left side. The associated sigmoidal conditions are undoubtedly primary, in many instances, as they are found in men although adhesions here may be due to infections of the vas but are also very frequently secondary to the disease of the tubes, ovaries and uterus, as they are frequently observed after definite infections of this tract.

72 *Simple Treatment for Corns. E. Griffith, New York.

72. **Treatment for Corns.**—In the method described Griffith depends on the macerating power of ordinary adhesive plaster to effect the result sought. A strip of this material from ⅜ to ½ inch (1 cm.-1.25 cm.) in width and 4 to 6 (10 cm.-15 cm.) inches long is to be applied in spiral fashion to the affected toe covering the digit from neck to nail. The degree of tightness of the application deserves consideration to avoid compression. However, the feelings of the patient when stepping on the foot will serve as an adequate guide in this matter. Instructions to cut through the plaster lengthwise or to soak off the entire dressing by immersion in a hot water foot bath affords ample protection in cases of undetected microbic infection. Soaking the foot for ten to twenty minutes in water at a temperature of 100 F., with gentle removal by rubbing with a piece of sterilized pumice stone or forceps of the crown of hardened epidermis shortens the time of treatment. Griffith contends that properly applied the dressing described should afford relief from the moment of its application, and may be worn continuously for from one to six or eight weeks, bathing seeming to unaffect the adhesive properties of the plaster after once having set. Removal of the dressing at the end of an adequate time reveals the cornus completely freed, when it may be picked out entire by means of a dressing forceps or after an additional soaking. A wisp of absorbent cotton held on by means of a narrow adhesive strap may be subsequently worn for a few days.

80 *Surgical Treatment of Cholelithiasis. W. J. Mayo, Rochester, *Minn.*
81 Primary Tumors of Bladder. W. Hutchinson, Montreal.

76. **Etiology of Cholelithiasis.**—In 145 cases of cholecystitis studied by Ryerson, gall-stones occurred in 55.8 to 58 per cent. of patients between the ages of 15 and 45. Adding to the above the number of cases in which symptoms started in that period, the percentage is increased to 65. Ryerson found that typhoid, which is recognized as one of the exciting causes of gall-stone formation, occurs most often in the early part of that period, and that the conditions of pregnancy and fibroids of the uterus, which are known to be commonly associated with gall-stones, are most common at that time of life. Gall-stones are not found at autopsy in any larger proportion of cases after 45 than before that age. Ryerson suggests that if gall-stones are formed as the result of a chronic infection of the gall-bladder occurring most commonly between the ages of 15 and 45, why should we not try to overcome this infection? We know that if a gall-bladder is emptied of stones and drained for a short period of time, that stones very rarely reform, as the cause of their formation, chronic infection, has disappeared. If this is the case, why should we not take the same steps when we know that a chronic cholecystitis is present, which will ultimately result in the formation of gall-stones? Will the patient ever get rid of the infection if we do not drain his gall-bladder?

The anatomic arrangement of the cystic duct, on account of the infolding of the mucous membrane in the form of valves in the interior, is of such a character that it is questionable whether it can provide sufficiently free drainage to the gall-bladder to rid it of its infection. The fact that we know that there exist "typhoid carriers" in whom the typhoid bacilli have been found in the gall-bladder twenty and even thirty years after infection, also shows us that this infection of the gall-bladder tends to persist unless steps are taken to relieve it. Not infrequently, in operating on the abdomen for symptoms suggestive of gall-bladder trouble, if the surgeon cannot palpate stones in the interior of the gall-bladder or in the ducts, he closes the abdomen without opening the gall-bladder. The symptoms of chronic cholecystitis are so closely identical with those of cholelithiasis that the gall-bladder, although showing no stones or peritoneal changes, such as adhesions, should invariably be opened and drained in such cases.

He considers the simple operation for uncomplicated gall-stones, with its mortality of 5 per cent., to be an entirely justifiable procedure as a means of preventing the years and years of symptoms which gall-stones are known to cause. He predicts that the day is surely not far distant when we shall advise immediate drainage of the gall-bladder, not only for gall-stones, but also for chronic cholecystitis, such as that complicating typhoid or other intestinal infection, and by so doing prevent the formation of gall-stones, with their years of chronic indigestion, repeated attacks of biliary colic and irritation resulting in malignant disease.

77. **Extirpation of Thyroid in Monkeys.**—The thyroid and parathyroids were extirpated by Halpenny and Gunn in eight monkeys. Briefly, the results were as follows: Experiment 1.—Remained well for three days; died on the sixth day, having shown no symptoms other than slight tremor and listlessness. Exp. 2.—Remained well for four days when some stupidity and paresis were observed. On the twelfth day there was some puffiness of the face. At no time was there any tremor or pronounced tetany observed. Died on the seventeenth day. Exp. 3.—Symptoms of tetany on the third day. Died on the seventeenth day in an emaciated condition. Exp. 4.—Had typical tetany on the seventh day. Died greatly emaciated on the eighteenth day. Exp. 5.—Typical nervous symptoms on the thirteenth day. This condition lasted with intermissions for five days. The animal then practically recovered and remained in good health till the sixty-third day, when paresis again occurred. On the seventy-first day it was found in a comatose condition, when a small dose of thyroid extract was given. After a few hours tetany supervened. The animal died the following day, seventy-two days after operation. Exp. 6.—No symptoms of any kind were observed till seventy-one days after the operation, when there was some malaise and loss of appetite. The monkey got steadily feebler and more apathetic until the eighty-first day, when it died, having shown no specific nervous symptoms. Exp. 7.—Remained well till the fifth day, when slight nervous symptoms came on. Remained in a state of moderate feebleness till the thirty-sixth day, when it had a distinct attack of tetany. From this the animal did not recover and died on the following day. After the final attack of tetany, a small dose of thyroid was administered. Exp. 8.—Symptoms similar to those of No. 7. On the thirty-sixth day the monkey was in a comparatively good state of health, although by no means free from symptoms. Three fairly large doses of thyroid extract were administered at intervals of several hours. Acute tetany supervened and the animal died on the fortieth day.

94 *Modification of Torek Combined Operation for *Removal of* Appendix and Cure of Right Inguinal Hernia. H. M. Cohen, Denver.
95 *Apical Pregnancy. C. B. Ingraham, Denver.

94. **Modification of Torek Combined Operation.**—Cohen's modification of Torek's operation deals with the disposal of the neck of the hernial sac. After the appendix has been removed and the peritoneum over it sutured, the ends of the suture uniting this portion of the peritoneum are left long. The peritoneum around the neck of the hernial sac is now bluntly loosened for a distance of about ¾ of an inch. Through the opening in the internal oblique and transversalis over the appendix, a forceps is bluntly pushed along between peritoneum and muscle until the neck of the hernial sac is grasped. The sac is then dislocated upward and tied with the ends of the peritoneal suture, which have purposely been left long. In this way the neck of the sac is not only doubly ligated, but is also dislocated by pulling it away from the weak internal ring, thereby more positively guarding against a recurrence of the hernia. Cohen has used this method in but two cases, both resulting in positive cures.

95. **Apical Pregnancy.**—In Ingraham's case the placenta was found situated in the right uterine cornu, extending two-thirds the distance on the right wall of the uterus. This was detached, broken up and removed with the ovum forceps. The right wall of the uterus was thin and pouched, the left wall was distinctly thicker. No septum as in a uterus bicornis unicollis was palpable. The morcellated fetus when reconstructed was 16 cm. in length, showing the pregnancy to be about four months in duration.

100. **Proper Use of Adhesive Plaster.**—In applying adhesive plaster directly to the skin Skillern takes pains to shave the hair. If the part has not been shaven, painful removal of the plaster is obviated by using refined medicinal benzin; it is cheap, antiseptic and cleansing, and rapidly volatile. Like turpentine, it is antiseptic, thus diminishing infection of hair follicles, and it readily dissolves the zinc oxid and removes the dirt which collects around the edges of the plaster. Often small pustules are exposed on removal of the plaster. Skillern finds that these may often be prevented by sterilizing the skin, even though imperfectly, with dilute alcohol, iodid of mercury or formaldehyd in solution, before applying the plaster, the idea being to sterilize as far as possible the hair follicles and sebaceous glands, through which bacteria commonly infect the skin. He believes the custom of storing strips on the wall within handy reach of the surgeon accounts to some extent for these little infections. To obviate this he prefers to tear strips himself from the original 5-yard roll, as this is much cleaner and permits the proper adaptation of the length and width of the strip to the case under treatment. Better retention is obtained by using a few broad, stout strips in place of many narrow ones, and the length of the strip should be gauged by the weight of the dressing. On immovable parts of the skin he uses, when possible, the flexible collodion and cotton-cocoon dressing, but on movable parts, such as the neck, this is stiff and annoying.

When applied to retain bandages in place, rubber adhesive-plaster strips may be used; as a rule, the narrower the better. Strips 3/16 of an inch in width usually suffice, are economical and more readily moulded to the part. These are best applied by simply following the turns of the bandage, which on the extremities usually describe a figure-of-eight. On cylindrical parts, such as digits and stumps, Skillern applies the strips so as to imitate the staves and hoops of a barrel. Where turns cross approximately at right angles to each other, as in the spica of the groin or shoulder and particularly in head bandages, far better retention is obtained by inserting pins so as to include the layers. This insures against vertical turns slipping sideways and horizontal turns slipping up or down. Strips may then be so adjusted as to cover the pins to prevent accidental scratches. In the skull-cap bandage he applies the coronal strips first, securing their ends by lateral fronto-occipital strips, it being important to place the latter strips well below the external occipital protuberance.

He has found the secret of retaining the spica bandage of the groin to lie not only in placing the ascending turns above the iliac crest, but in inserting pins through the cross layers and ½-inch strips of adhesive plaster at both edges of the bandage, and throughout its entire length. It is most important to place the inner strip as close as possible to the origin of the adductor longus tendon, much better retention being obtained in this way. If a wet dressing has been used it is necessary, and in any event always desirable, to interpose waxed paper between the gauze and the cotton compress which Skillern invariably places under the bandage to equalize the circulation.

105. **Coincident Intra- and Extra-Uterine Pregnancy.**—The history of Hirst's case is as follows: Mrs. M., aged 32, married ten years, two children; one miscarriage four years ago. Menses regular but scanty and short in duration; in January unusually scanty; in February a week late. *Patient had* had pain in ovarian region for some time but for last two weeks very severe and of a colicky character. A vaginal examination revealed a large tubo-ovarian mass on the right side and in Douglas' pouch. Diagnosis was ectopic gestation. An operation was performed the following day. Free blood in abdomen and right-sided tubal gestation were found. Ten days after operation there occurred an abortion of a six-weeks' embryo and sac from the uterus. The patient recovered.

113. **Mechanism of Pressure in Production of Vertigo.**—In cases of recurrent vertiginous attack with inadequate evidence of an intralabyrinthine or of an accessible extrinsic pressure factor, it seemed desirable to Blake to test the effect, on the line instituted by Babinski, of decrease of intracranial and, correspondingly, of intralabyrinthine pressure by some means which would leave the auditory apparatus intact, an additional incentive to such a series of investigations being previous experiences in disturbances of intralabyrinthine pressure, incident to investigations in regard to the removal of the stapes. Under these considerations, in a series of adult cases in which the extrinsic pressure factor was at a minimum, or absent, lumbar puncture was practiced with results thus far sufficiently favorable to warrant a continuation of the investigation. In no instance were there more unfavorable consequences than severe headache of several days' duration in three instances; in all of the patients treated there has been a temporary amelioration of the condition, and, in the majority, entire relief from the vertiginous attacks, during a period of from a few months to three years, the latter being the major limit of observation.

In two cases in which the attacks recurred within a year the onsets were less severe and the complex incomplete, and a repetition of the lumbar puncture was followed by entire relief up to the date of the last observation.

In all instances the withdrawal of fluid ranged from 10 to 15 c.c., and the cases were kept under immediate observation for several days.

127. **Intestinal Parasites Among Immigrants.**—Of the 412 immigrants of all nationalities examined by Manning 166, or 40.2 per cent., were infected with one or more intestinal worms. Of the 282 males 115, or 40.7 per cent., and of the 130 females 51, or 38.4 per cent., were infected. Ninety-one, or 22 per cent., were *infected with Trichuris trichiura*, of whom 68 were males and 23 females, giving the rates of 24.1 and 17.6 per 100, respectively. The rate of infection with this parasite was highest among those from Russia; the rates for the different countries were 18.1 per 100 for Austria-Hungary, Greece 20.9, Italy 22.2, Russia 32.3, and Turkey 15 per 100. It was the most frequent parasite found among those from Austria-Hungary and Greece, and among these the males were more frequently *infected than the females.*

The *Ascaris lumbricoides* was present 118 times, or 28.6 per 100. Among the males 80, or 28.3 per cent., and among the females 38, or 29.2 per cent., were infected with this worm. The rates for the different nationalities were: Austria-Hungary 15.1, Greece 18.6, Italy 43.5, Russia 34.2, and Turkey 28.3 per 100. Italy showed the highest rate for this parasite. This is the most frequent parasite found and occurs more frequently among the females than the males, although Italy, Russia and Turkey show a higher rate for the males.

Only 1 *infection with the Oxyuris vermicularis* was found, but no doubt the reason for not finding it more frequently was due to the rarity with which the eggs are found in the feces.

Two cases of infection with the *Strongyloides stercoralis* were found, 1 in an immigrant from the British West Indies and 1 from Russia. The rate of occurrence of this parasite for *all immigrants examined* was 0.48 per 100. Both of these cases were in males, and in the case from the West Indies his anemic condition suggested the suspicion of hookworm infection, but after repeated examination of several fresh stools, no ova were found, but numerous larvæ of the Cochin China worm.

The Italian boy infected with the *Ankylostoma duodenale* was the only case of hookworms found. The rate of occurrence of this parasite among all the immigrants examined is .24 per 100.

Seven infections with tapeworms were found, 1 a case of infection with the *Dibothriocephalus latus* in a Russian woman, 3 males and 2 females among those from Turkey, and 1 female child among the Greeks. Two of those among the Turkish men were *Tænia saginata* and in the case of the 4 others the species were not determined. The rate of prevalence of the *Dibothriocephalus latus* among the Russians was .95 per 100, the rate *of Tænia* among the Greeks being 2.3, and among the Turks 9.4 per 100.

Among the 76 immigrants under 15 years of age there were 58 infections, or 76.6 per 100. Among the 259 between 15 and 31 years there were 128 infections, or 49.4 per 100. Among the 70 between 31 and 50 years there were 30 infections, or 42.8 per 100. Among the 7 over 51 years of age there were 4 infections, or 57.1 per 100. This shows that among all the immigrants examined the heaviest infection occurred in early life and tends to diminish with age. The rise in the case of those over 51 years may be due to accident on account of the small number examined.

Among the 412 immigrants there were 220 infections, giving the rate of prevalence of intestinal parasites as 53.39 per 100. Among the 282 males there were 155 infections, or 54.96 per 100, and among the 130 females there were 65 infections, or 50 per 100, showing that intestinal worms are slightly more frequent among the males than among the females.

130. **Tinea Versicolor in Three Sisters.**—The three sisters whose cases are reported by Knowles and Corson were all born in Russia although Philadelphia has been their place of residence for some years. They are healthy, but being extremely poor their cleanliness was not such as might have been desired. They occupied the same bed and occasionally used the *same* towel.

4. **Lymphatism in East.**—Whitmore found sixteen cases of lymphatism in 565 bodies examined. In five, and probably in six, of the cases quoted the deaths were due to causes other than any peculiar dyscrasia of which the persistence of the thymus gland and the general hyperplasia of lymph tissue are the outward and visible signs.

5. **Bilharziosis.**—The first case reported by *Madden* was *one* of bilharziosis of the spermatic cord simulating tuberculous epididymitis. In the second case hemospermia was the first symptom of bilharziosis.

7. **Influence of Salicylates on Thyroid Activity.**—Three cases are cited by Waller to prove his contention that salicylates have a powerful influence against thyroid activity. For instance a robust adult had an acute tonsillitis. He had stuck to his work for three or four days when Waller first saw him one morning. He had then taken to his bed with a pulse-rate of 120 and temperature 102 F. He had headache and aches and pains in the limbs severe enough to suggest rheumatism, but possibly only influenzal. He was given a mixture containing 15-grain doses of sodium salicylate and ½-grain doses of compound tincture of cinchona. But owing to variations in the size of the domestic tablespoon, he repeatedly took a larger dose, roughly, 20 grains of salicylate and 40 minims of bark, every four hours. He then had a (morning) pulse-rate of 48 and temperature of 96.4 F. He had sweated profusely the first night, and his bowels were obstinately constipated, resisting strong doses of aperient. The pulse and temperature remained at this low level all the next day, and the bowels were still obstinately constipated in spite of aperients, though the salicylate mixture had been left off. Thyroid, 2½ gr., twice a day, was then given for two days, and the temperature again rose, this time to nearly 101 F., and the pulse to 98. The throat progressed rather slowly in spite of energetic antiseptic treatment which had given excellent results in other cases. The patient returned to work twelve days after Waller first saw him, when in spite of full doses of strychnin he had a very soft dicrotic pulse of 76 and a blood-pressure of only 100 mm. mercury.

8. **Mediastinal Causes of Chronic Cough in Children.**—Chronic enlargement, sometimes no doubt associated with tuberculous caseation, of the lymph-nodes at the bifurcation of the trachea is believed by French to be a cause in these cases of chronic cough. The bronchial node immediately below the right bronchus is affected far more frequently than is the node on the left side, and the right phrenic nerve is frequently seen to be displaced by the enlarged lymph-node in such a way as probably to be much irritated by it and thus lead to attacks of purposeless coughing—that is to say, coughing which does not succeed in bringing up any sputum. In a certain number of cases it is possible to demonstrate the enlargement of this right bronchial node by means of the Roentgen rays. French suggests that the attacks of coughing which are so troublesome in some heart cases are to be explained by irritation of the phrenic nerves in a similar way, by their being displaced and stretched by the dilated and hypertrophied heart. The importance of realizing that enlarged bronchial lymph-nodes may be the cause of persistent coughing in children is that the enlargement is generally tuberculous, and therefore the correct treatment is to adopt the general hygiene best adapted to the relief of a tuberculous infection together with measures calculated to prevent the swallowing of more living tubercle bacilli, an end to be accomplished either by obtaining milk from cows that have been tested satisfactorily with tuberculin, or else by making sure that any tubercle bacilli in the milk have been killed by efficient sterilization, preferably by thorough boiling.

9. **"Comforter" Otitis Media.**—The way in which the "comforter" acts is by introducing oral sepsis. This, in Bowen's opinion, is the crux of the matter. The "comforter" is at fault only in so far as it introduces sepsis leading to what are probably catarrhal processes, giving very little, if any, signs or symptoms in the mouth, oropharynx and nasopharynx; but once they spread by the tube to the middle ear, the lack of drainage quickly becomes felt and suppuration often results. That catarrh alone may result, with painful distention of the middle ear, is probable from the occurrence of pain in the ears in some babies who never get discharge coming from the meatus. Even if it gets no further than a painful catarrhal process, however, it is capable of doing considerable damage in a small enclosed space like the middle ear.

10. **Treatment of Torticollis.**—Roth calls attention to the fact that after torticollis has been treated by tenotomy no retentive apparatus is necessary. After division of the muscle and fascia by the open operation, the head is firmly manipulated into an overcorrected position. The child is then put back to bed with the head between sandbags, and on the second or third day is allowed up and gentle passive movements are begun. On the fifth or sixth day active movements take their place, and after removal of the stitches the mother is shown how to superintend the carrying out of these movements at home for five minutes twice a day.

16. **Treatment of Constipation.**—The importance of hygienic measures, exercise and diet are pointed out by Sawyer. For a case of habitual constipation which does not cure without medicines, his favorite remedy is Socotrine aloes, suitably combined and exhibited as a pill, at bedtime. Myrrh and aloes and cassia can, he says, still make coprostatics glad; myrrh, with its old repute of giving an impetus to the digestive organs, and an increase of muscular power to the digestive canal, Socotrine aloes and cassia pulp, of each equal proportions, made into a pill of the weight of 5 gr. with syrup or castor oil. One pill or more may be given for a dose, as found to be needed, and their administration should be gradually reduced and omitted altogether so soon as may be. He emphasizes that no case of habitual constipation can be treated by rule of thumb.

18. **Treatment of Hay-Fever.**—Considering all the cases generally, there seems little doubt in Freeman's mind that there has been a distinct amelioration of symptoms in all his cases treated by pollen vaccine. This improvement took several forms: a greater freedom from attack, the attack not so bad as in former years, and the attack sooner over; the constitutional disturbance not so great; less asthma. The people who had already developed hay-fever when they commenced were, perhaps, the most generous in their comments, possibly because they had recently had a reminder of what hay-fever was like.

20. **Traumatic Rupture of Abdominal Viscera.**—Excluding cases admitted moribund, out of ten patients with ruptured liver, intestine, pancreas, or spleen, the pulse-rate when they were first seen was in one case 100, in another 99, and in seven about normal. In one it was only 30. In every case of rupture of any abdominal viscus in which the pulse-rate on admission exceeded 100, the patient died within twenty-four hours. Short says it is often mentioned that the volume and tension were good. The text-books usually state that the pulse-rate will rise if there is a serious injury. This was true in at least six cases, but in one of ruptured liver it fell from 84 to 62. The temperature seems to be of more value. It is only recorded nine times; in five of these it was markedly subnormal. Pallor or anxious appearance is often remarked on. Abdominal pain and rigidity were almost constant, except in the tragic and deceptive cases. Vomiting was not usual. Only one patient vomited blood. The diagnosis was usually made by observing that after some hours the appearance, the abdominal condition, and the pulse did not improve; in many there was a decided change for the worse.

30. **Residual Urine in Old Men.**—The object of the treatment suggested by Miller in these cases is twofold, to improve the muscular tone of the bladder by exercise and to train the bladder to empty itself. to enable it to acquire a good habit. He advises those having residual urine after passing water in the usual way to wait a minute or two and then try again. Practice this as frequently as possible, till only a very small quantity can be squeezed out (say, half an ounce). When this point has been reached, twice or thrice daily may suffice. The most important times are before going to bed and on rising in the morning. On these occasions it may be advisable. at first, to make three, or even more, efforts so as to make sure of thoroughly emptying the bladder. It is not advisable to wait too long before making the second effort. About one minute is generally quite sufficient, certainly not more than two; because after the act of expelling the urine the bladder may quiet down if the patient waits too long, and a considerable effort may be required to start the flow again.

32. **Prognosis of Heart Disease.**—Dally says that all things being equal. the descending order of gravity of the chief valvular lesions may broadly be stated as follows: (1) Aortic and mitral disease combined, (2) aortic regurgitation, (3) mitral stenosis, (4) aortic stenosis, and (5) mitral regurgitation.

60 *Ovarian Cyst with Torsion of Pedicle, Giving Rise to Unusual Symptoms. W. D. MacFarlane.

55. **Extraperitoneal Cesarean Section.**—So far as Tweedy's experience goes he would not consider extraperitoneal Cesarean section an alternative to classical Cesarean section, but rather its complement.

56. **Expulsion of Placenta Before Birth of Child.**—The points of interest in the three cases cited by MacFarlane are: (1) The premature expulsion of the placenta in all pointing to placenta prævia; in one case the last two pregnancies were complicated by placenta prævia. (2) The shape and unusual length of the placenta in two of the cases. It is not unusual to have the placenta crescentic in shape when situated near the os internum. (3) The uniform presence of areas of placental infarction on the maternal surface. (4) The presence of hydramnios in two of the cases. (5) A history of endometrial involvement in all the cases. (6) The absence of hemorrhage either before or after the expulsion of the placenta. The puerperium in these three cases was normal.

60. **Ovarian Cyst with Torsion of Pedicle.**—MacFarlane's patient gave a history of kidney pain of seven years' duration, and of three recent attacks of pain of an unusually severe nature accompanied by sickness and vomiting. The pain was most acute in the left lumbar region, followed the course of the left ureter, and there was dysuria and very frequent micturition; at no time had there been evidence of hematuria. The pain had at no time any relation to menstruation and was not accompanied by any bloody discharge from the vagina. All the thoracic organs were normal. On palpation, a tense, cystic swelling was found occupying the middle line from the symphysis pubis to within three fingers' breadth of the umbilicus; it did not seem to have much mobility and was painless on pressure or attempted movement. The percussion note was dull over the swelling and resonant in flanks. Omentum and intestines were densely adherent all over the surface of the tumor. The rectum and right uterine appendages were also firmly attached to the cyst wall. After removing the adherent omentum and bowel from the tumor wall, a long thin pedicle with three turns from left to right was found attached to the tumor, which proved to be a unilocular cyst of the left ovary.

64 *Digitalis. J. Mackenzie.

64. **Digitalis.**—A careful and thorough clinical study of digitalis was made by Mackenzie in forty-three cases, which are reported in detail, and for these the original article (covering 113 pages) must be consulted. Mackenzie summarizes his findings as follows: The careful analysis of the symptoms of patients to whom digitalis has been administered brings out the fact that individuals react differently to the drug. So far as the heart is concerned, the difference is partly dependent on the nature of the lesion with which the heart is affected. Patients with auricular fibrillation are more readily and more markedly affected than patients with the normal rhythm. Digitalis, in a proportion of patients with normal rhythm, affects the auriculoventricular bundle more particularly, producing partial heart-block. It is suggested that the susceptibility of patients with auricular fibrillation may result from the tendency of the digitalis to affect the bundle, the change in the auricular condition rendering the bundle more susceptible to the influence of the digitalis. It is possible that in slowing the heart's rate, the digitalis acts by stimulating the vagus nerve. Digitalis tends to induce auricular fibrillation. In two cases of tachycardia, arising from an abnormal source, digitalis caused the heart to revert to a normal rhythm, first inducing fibrillation of the auricle. The diuretic effects of digitalis may be produced with no perceptible change in the heart.

68 *Suppuration and Gangrene of Uterine Fibromas. P. Lecène.
69 Lymphoid Growths in Chronic Salpingitis. Meriel and Bassal.
70 Diathermia in Gynecology. (Nouvelle méthode de thermothérapie dans les maladies gynécologiques.) S. Flatau.
71 Dry Bolus Alba in Treatment of Catarrhal Conditions in Female Genitalia, Etc. (Traitement des écoulements chez la femme.) M. Nassauer.

68. **Gangrene of Uterine Fibromas.**—Lecène reports seven cases of fibromas with various complications, such as aseptic decay, suppuration or putrefaction of the fibromyomas. He has had only one case of infection and suppuration of a fibroma in the uterus, among the ninety-five *uterine fibroma* cases in which he has operated in the last six years. The infection was from the colon bacillus and probably of intestinal origin; the general health was much impaired, the pulse rapid, with fluctuating high fever. In one case of gangrenous fibroma he sterilized the vagina with iodin and sutured the cervix of the uterus to close it water-tight so that he was able to remove the uterus without escape of infectious matter. The gangrenous fibromas have a special dregs-of-wine color which extends through the internal genitals as he shows in a colored plate.

73 Technic for Testing the Hearing in Young Children. (Technique de l'examen auditif.) P. M. Constantin.

72. **Acquired Tolerance to Toxic Substances.**—Roger states that the strength of the solution and the rapidity of the injection are important factors in the effect of experimental injection of poisons, as he shows by reports of several series of researches. They suggest the necessity for studying from the bottom anew the toxicologic action of extracts of organs. Champy and Gley have recently reported that injection of a dose of extract of corpus luteum, not immediately fatal, immunizes the animals in less than fifteen minutes, so that they will bear without harm injection then of ten times the dose fatal for the controls. They have coined for this rapid immunization the term "tachyphylaxis," and Roger reports similar experiences with rabbits injected with extract of lung tissue. The serum of a rabbit thus immunized does not enhance the resisting powers of a previously untreated animal. He calls attention to this negative result as showing the marked difference between this rapidly acquired tolerance and the slow immunization which can be acquired against microbian poisoning. He thinks the more proper term would be "tachysynethia," to indicate rapidly becoming accustomed, in contrast to the phenomena connected with antimicrobian vaccination. This factor of the organism becoming accustomed to an organ extract has been overlooked in the research hitherto on the internal secretions of the various organs.

82 Pathologic Changes in the Reflexes After Trauma of the Spinal Cord. Mattirolo.

76. **Tuberculous Pericarditis.**—Jacob and Chavigny report a case of tuberculous pericarditis with much effusion in which the diagnosis was long dubious; pericardotomy alone cleared up the case and has apparently cured the patient. This affection has no pathognomonic signs or symptoms; even puncture may prove misleading and do actual harm while from the therapeutic point of view it is inadequate and has to be inevitably followed by pericardotomy sooner or later. They advocate therefore pericardotomy as the routine procedure at the start without wasting time on other measures. Their patient was a waiter, 23 years old, with a tendency to asphyxia and cyanosis but change of position did not modify the position of the heart. The pulse was of the paradox type; the area of heart dulness was not enlarged but it was absolute and roentography showed the heart shadow enlarged, with round outlines and no concavity. There was no edema, dysphagia or albuminuria. The sudden intense dyspnea was evidently of cardiac origin but it was impossible to say whether it was due to acute dilatation, the terminal phase of an unsuspected endocarditis or to a pericardial effusion. The patient's strength was kept up with inhalation of oxygen and injection of ether and camphorated oil, and the next day pericardotomy was done under cocain local anesthesia; the benefit was prompt and marvelous. The incision in the skin was sutured without drainage but the incision in the pericardium was left untouched so that any further effusion might drain away of itself and possibly induce a kind of autoserotherapy.

78. **Postapoplectic Mania.**—Benon applies this term to a secondary mania developing as the patient is recovering from the phase of weakness of muscles and mind which follows a cerebrospinal hemorrhage. He reports two typical cases. The first patient was a woman of 82 and the muscular weakness lasted about two weeks after the apoplexy; then followed a week of increasing strength and liveliness, gradually amounting to actual mania with insomnia. This phase lasted for twenty or twenty-five days and gradually subsided, normal conditions then being restored except for persisting hemiparesis. The second patient was a man of 42, and the asthenia lasted three or four days and the mania ten or twelve, but there is still a little mental impairment. In three other cases the asthenia and mania recurred occasionally and the mental condition compelled institutional care in some. These patients were 42 and 43 years old and their affection merges into periodical depressive mania. Another patient had an attack of melancholia at 27 and a cerebral hemorrhage at 32, followed by recurring attacks of asthenia and suicidal depression but no actual mental impairment. In conclusion Benon reviews the literature on the subject of apoplexy in the history of the insane, and warns that institutional care is seldom necessary for persons developing this transient mania after a cerebral hemorrhage, as it generally subsides spontaneously in a few weeks or months. At the same time it may blend into periodic depressive mania. He also remarks that the alternations of gay excitement and depression in the insane are often merely phenomena indicating phases of asthenia or hypersthenia. He adds further that these phenomena should not be taken for signs of mental impairment.

Semaine Médicale, Paris

September 6, XXXI, No. 36, pp. 421-432

83 *Treatment of Placenta Prævia. R. De Bovis.

83. **Treatment of Placenta Prævia.**—De Bovis discusses whether operative treatment of placenta prævia is justified, reviewing international experiences in this line. The main point is to arrest the hemorrhage at any price, even at the price of an operation; then to deliver the woman without haste and without force. This latter principle does not seem to be always understood; because it is important to hasten to arrest the hemorrhage, it does not follow by any means, he insists, that delivery must be hastened. If an inflatable bag has been introduced or version done, the rule should be *Tendre et attendre*, that is gently press the bag or the breech of the fetus against the lower segment of the uterus, but wait patiently for spontaneous expulsion. This advice, he declares, formulated by all experienced obstetricians, should be printed in the heaviest type in the works on the practice of obstetrics; unfortunately there is generally not even a reference to such advice. It is rendered necessary by the extreme friability of the lower segment in these conditions. This also is what contra-indicates instrumental dilatation, which should be formally repudiated with placenta prævia. Even dilatation by the hand has entailed fatal laceration of the cervix as van Tussenbroek emphasized anew in 1908. De Bovis' own practice is to insist on absolute quiet, with rupture of the fetal membranes at need, and irrigation of the uterus with hot water, using 7 or 8 liters of water at least, at a temperature of 45 to 48 C. (113 to 118 F.), and recommencing the irrigation if necessary until the hemorrhage has been arrested. This method of treatment is tedious, but it does not infect the parturient like a tampon nor expose to mishaps, such as are liable with version and introduction of the inflatable bag, and as it often permits the bag of waters to be left undisturbed, it affords better chances for the life of the child. When merely tepid water is used or insufficient amounts of the hot water, the tendency to hemorrhage is promoted instead of checked. His experience with seventy cases in ten years without a fatality is a fine record, and although he has had two deaths recently, the patients brought in practically moribund, yet this is a mortality of only 2.7 per cent. in his total seventy-two cases of placenta prævia in the last eleven years.

88. Epidemic Poliomyelitis in Northern Germany.—During 1909 and 1910 there were three extensive foci in Germany at the same time as epidemics occurred in Austria and this country. Besides these large foci, a small epidemic of 132 cases in all occurred in the Schleswig-Holstein province in northern Germany, and Meyer here presents the results of careful research into conditions in this latter focus. The intermediation of healthy germ-carriers in propagating the disease was particularly evident in this epidemic, conditions in this respect being almost identical with those of epidemics of cerebrospinal meningitis. The symptomatology and prophylaxis are discussed in detail.

91. Operative Interference with Circulation in the Lung and Its Curative Influence on Tuberculous Processes.—Practical experience has convinced Tiegel that partially obstructing the circulation in the lung does not materially alter its histologic structure and functioning but it has an unmistakable inhibiting influence on the development of tuberculosis. The method promises to apply also to tuberculous processes in the kidneys, and he is now experimenting in this line. His research was all done on rabbits; dogs are not susceptible enough to the inoculation of tubercle bacilli to answer for the experiments. He induced the stasis in the lung by ligating the pulmonary vein with a fine wire introduced through the fourth or fifth interspace under some differential-pressure procedure. He gives illustrations of the treated and untreated lung, instructively showing the tendency to heal of tuberculous processes as the lung grew tougher and harder under the influence of the stasis.

99. Intratracheal Insufflation for Operations on the Lungs.—Schlesinger has been operating on the lungs of dogs with the Meltzer and Auer intratracheal insufflation method, and declares that the simplicity of the method will render it superior to all others if the technic can be perfected a little farther. The main drawback is that it requires deep general anesthesia. According to his experiences severe injury may be inflicted if the anesthesia is not deep enough to relax the animal entirely. He does not consider it fully established yet that the insufflation never harms the respiratory organs. The influx of air into a yet unopened pleura is by no means an altogether harmless occurrence. The change of catheters during the operation might also prove dangerous in the clinic. The chief advantages of the method he enumerates as its simplicity, inexpensiveness, convenience and absolute prevention of aspiration of vomit, etc., while the surgeon can work on a stationary lung.

103. Drainage of the Lateral Ventricles in Hydrocephalus.—Payr states that in the last three years he has operated in fifteen cases of hydrocephalus by various technics aiming to open a connection between the ventricle and the venous circulation and thus drain away the excess of fluid. The youngest patient was 6 months, the oldest 20 years old. The hydrocephalus was completely cured in 50 per cent. of the eight patients who survived the first few months. The fatalities were due to too rapid evacuation of the fluid in two cases, to primary infection in one and secondary infection months later from a fistula in four others. The cases were naturally all of the severest types. In four he drained into the longitudinal sinus, in four into the jugular or facial vein; in seven into the subarachnoid or subdural space or into the loose connective tissue under the temporal muscle. He used for the drain a segment of calf artery for the portion within the brain, piecing this out below with a segment of the patient's own saphena run through under the skin. Necropsy in the fatal cases showed that the drain was constantly permeable. He regards the results on the whole as very encouraging, the failures being probably avoidable by improved technic.

104. The Thyroid with Exophthalmic Goiter.—Kocher reports the results of recent research on the physiology and chemistry of the thyroid gland as studied on the thyroids removed from thirty-five patients with exophthalmic goiter. His experience is now so extensive that from the clinical manifestations alone he is generally able to predict the exact histologic chemical conditions that will be found in the thyroid. They are usually of four different types and each corresponds to a special clinical type of the disease, as he shows by examples. Particularly interesting are the results of transplantation of scraps of a Basedow thyroid into persons suffering from deficient thyroid functioning. He has been doing work in this line—implanting the scraps in the bones—since 1898 and the benefit has been direct and permanent in certain cases. Desiccated Basedow thyroids have also been used in treatment of certain other patients and the result on the metabolism carefully studied. The effect seemed to be the same as when normal thyroids are administered—this testifies against the assumption of perverted thyroid functioning in exophthalmic goiter. The Basedow thyroids seemed to influence the metabolism more effectively the larger the iodin content of the gland. This was also observed in patients with myxedema given ordinary thyroid treatment. The proportion of iodin in the Basedow thyroid varies in wide limits, being always far above or far below normal range, both absolutely and relatively.

115 *Erysipelas with Afebrile Course. E. v. Czyhlarz.

108. Tumors in Meckel's Diverticulum.—In the first of the three cases reported the diverticulum was the seat of a large sarcoma. Tschiknawerow has been able to find only one case like this on record; the patients were 62 and 72 years old. In the other cases the diverticulum was the seat of what seemed to be an accessory pancreas or of abnormal proliferation of the crypts of Lieberkuhn.

109. **Rhizotomy for Gastric Crises in Tabes.**—Zinn reports a case in a man of 43 who was relieved at one stroke of intolerable gastric crises by the operation. After five months they recurred in a brief and mild form, once or twice a week, but disappeared again during the seventh month. In the majority of the twenty-eight cases published to date there has been recurrence later of the crises in a mild form, but the operation has been of life-saving importance in a number of cases.

115. **Afebrile Erysipelas.**—Czylharz states that he has had twenty-nine afebrile cases among his 324 cases of erysipelas during the last year at Vienna, all in women.

128 Case of Hematometra in Accessary Cornu of Uterus Bicornis. F. Sieber.

117 and 118. **Tuberculin Treatment in Surgical Tuberculosis.**—Wilms concludes from his clinical experience that the fungous forms of tuberculosis generally give a negative cutaneous tuberculin reaction. The cutaneous test therefore is no clue to diagnosis or prognosis unless the reaction is positive. On the other hand, with a fistulous or suppurating tuberculous process a negative reaction indicates a condition of cachexia. He has found tuberculin treatment especially advantageous in the forms of fungous tuberculosis giving a negative Pirquet reaction; the tuberculin treatment aids powerfully the natural tendency to heal. The slight reaction in such cases enables the dose to be rapidly increased. Combined treatment with tuberculin, roentotherapy, etc., is going to supersede surgical measures in treatment of tuberculosis, he thinks, more and more each year. The task is not only to remove the focus by an operation but to make the organism more resistant to reinfection. He is convinced that the cure of a tuberculous glandular process by conservative measures leaves the patient in better condition than when the lymphoma has been early removed. In the first case the body has been rendered strong by its struggle with the glandular tuberculosis and is thus more resistant against the unavoidable opportunities for new infection; while in the other case the body is equally sensitive as before to new infection and recurrence is almost inevitable unless tuberculin treatment comes to its assistance. Wilms remarks in conclusion that the scrofulous glandular swellings in youth may represent the period during which the organism is immunizing itself against the ubiquitous tuberculosis infection. Consequently he pleads for greater reserve in removing these protecting and battling organs. If an operation is indispensable on account of suppuration then the body should be reenforced by a course of tuberculin.

119. **Intracutaneous Tuberculin Test.**—Engel declares that this technic has numerous advantages over the other tuberculin tests; the technic is simple and the dose can be graduated while the reaction is easy to recognize and the inconvenience for the patient is minimal. He used the technic without knowledge of Mantoux' intradermal reaction. The latter uses 1 drop of 1 to 5,000 solution of tuberculin, but Engel uses 1 drop of a 1 to 1,000 solution of old tuberculin and, if no reaction follows, increases the strength to 1 per cent., 10 per cent. and 100 per cent. in some cases, some of the patients finally reacting to the latter dose. The subcutaneous tuberculin test fails with febrile patients, and the cutaneous with patients whose susceptibility to tuberculin is reduced, but the intracutaneous method succeeds when these others fail. When there is a morbid dread of tuberculosis, the intracutaneous reaction enables the last trace of uneasiness to be dispelled with mathematical certainty if there is no reaction to the stronger concentration. He cites a number of instructive cases to show the superiority of this technic in various puzzling conditions, as in the case of a cachectic child with meningitis in which this test positively excluded tuberculosis.

136 Scarlet Fever and Chronic Nephritis. Stroink.

129. **Prolapse of Urethra in Little Girls.**—Brüning reports a case of the sudden prolapse of the entire mucous lining of the urethra, without apparent cause, in a healthy girl of 8. Study of the literature on this subject shows that this occurrence is observed in girls only in early infancy and beween the ages of 8 and 12. Hemorrhage accompanied the prolapse in 41 per cent. of the seventy-six cases he has found and tabulated. In a large proportion of the cases the prolapse was not recognized and dire results followed treatment based on a mistaken diagnosis. The child should be kept in bed and astringent and cauterizing measures should be applied after reduction. If these fail or if the prolapse is total, he advises resection of the sagging portion and suture. The operative loss of blood has always been slight.

133. **Active Immunization in Prophylaxis of Diphtheria.**—Blumenau states that 348 children with measles or scarlet fever were given prophylactic injections of 500 or 600 antitoxin units as soon as they entered the contagious disease ward, and the injection was repeated each two weeks afterward. Nineteen of the children, that is, 5.5 per cent. developed diphtheria later, and signs of serum sickness were evident in 18.4 per cent. As these results were not considered satisfactory, Dzerjgowsky devised a method of inducing active immunization which seems to be promising. A wad of cotton impregnated with diphtheria toxin was introduced into each nostril alternately for an hour each day for ten days. In experiments on adults and on seventeen children it was found that there was marked production of antitoxin by this method. Experimental research indicates that the immunity thus acquired may last for months and years. The method may perhaps be advantageously combined with passive immunization by injection of antitoxin when rapid action is desired. The diphtheria toxin was diluted with twice the amount of salt solution in a later group of eleven children to avoid by-effects, and the tampon was left in the nose only half an hour every third day. There was no injury of the mucosa with this milder technic, while the antibody production was fully as marked as in the first group.

134. **Curability of Tuberculous Meningitis.**—Archangelsky reviews the five cases on record of recovery from tuberculous meningitis, and reports a case from his own experience. In

all the tubercle bacilli had been found in the cerebrospinal fluid or the biologic reactions had been positive. Repeated lumbar puncture had been one of the factors in the cure in his case, supplemented later by sodium iodid. These six cases are the only ones of which he knows in the last ten years.

138. **Physical Treatment of Rachitis.**—Kirchberg is chief of the Berlin massage institute, and he reports remarkable benefit from physical therapy in the treatment of rachitis, especially stimulation of peristalsis by massage of the abdomen which also has a favorable influence on the musculature of the abdomen and diaphragm. Stimulation of the skin by rubbing through a rough towel, air baths and massage of the skin to promote the circulation, all cooperate in notable improvement in the general health. He warns that actual scoliosis never retrogresses spontaneously, and urges the necessity for watching over infants to prevent its development. Lange has insisted that the foundation for curvature of the spine is frequently laid before the child is 1 year old by the way in which it is carried in the arms. In the florid stage of rachitic scoliosis passive movements and correction should be supplemented by breathing exercises; these are especially useful in preventing the fixation of the spine in scoliosis. One of Kirchberg's exercises has the child lie prone on a hard bench or bed and breathe deep with a long pause between inspiration and expiration, while the masseuse presses one shoulder and the pelvis of the child down firmly, so that the ribs have to be lifted upward and backward and thus induce vigorous movements in the joints of the spine. As a rule the exercises should be done with the trunk exposed, in front of a mirror, several times a day, up to half an hour at a time. He has the children breathe deeply as each of the gymnastic exercises is done.

139. **Momburg's Belt Constriction in Obstetrics.**—Fuchs reports two cases in which the remarkable advantages of this procedure to arrest obstetric hemorrhage were clearly evident. The constriction not only avoided all danger of excessive loss of blood but it also stimulated the uterus to healthy contractions. In his third case, however, the constriction had such an injurious action on the heart that it gradually failed and the patient died a few hours after the belt had been removed. The trouble in this case was a hydatidiform mole, so large that it required the constricting tube to be applied unusually high, above the level of the umbilicus. He draws the lesson from this case that this method is contra-indicated, especially raising the pelvis therewith, if the heart has been debilitated by considerable loss of blood. Also that the release of the constriction is the critical part of the procedure. On the whole, he does not think that this belt constriction is destined to extensive application in gynecology or in obstetrics except for the cases in which the belt can be applied as the first and most promising measure to arrest severe hemorrhage, especially from lacerations.

153 *Streptothrix Mycosis of the Lung. E. Liek.

146. **Chronic Tuberculous Meningitis.**—Strasmann reports a case of meningitis in a man of 38 which had run an extremely slow and protracted course, presenting symptoms apparently typical of the syndrome induced by a tumor in the hypophysis. On this assumption an exploratory trephining operation was done seeking to relieve the intolerable headaches, but no tumor was found and the patient died twelve days thereafter, about three years after the first symptoms of trouble. Necropsy disclosed a chronic diffuse tuberculous meningitis involving especially the chiasm and optic nerve. He publishes the case in detail to warn others against such pseudotumor cases. Hildebrand operated in a similar case and the tuberculous process healed afterward. In Strasmann's case the man had had for eight years a skin affection resembling lupus erythematodes, and he gradually became very obese, languid and somnolent. During the last year there had been recurring, intense headache and constipation, the papillæ were blanched and the somnolency kept increasing, and vomiting and dizziness occurred at times. The Wassermann reaction was negative and the headaches were not of the nocturnal type and there were no signs of inherited or acquired syphilis. Further testimony against syphilis was the chronic progressive course of the symptoms without any marked fluctuations and without any tendency to paralysis or irritation of all the basal cranial nerves. When the microscope revealed tuberculosis it was a great surprise, as there had been no fever nor high pulse-rate, no rigidity or pain at the back of the neck and none of the usual symptoms of trouble at the base of the brain, while the patient had kept well nourished throughout the three years' course of the affection.

147. **Shutting Off Part of Circulating Blood and Effects of the Procedure.**—Zoeppritz writes from the surgical clinic at Kiel in charge of Anschütz to report the results of sequestration of the blood in the extremities as a preliminary to operations. In 23.2 per cent. of the 112 cases the bleeding was exceptionally slight, in 30.3 per cent. slight, and in 46.5 per cent. no effect on the operative hemorrhages could be detected. He classifies the operations according to their site and the amount of hemorrhage. The influence of the sequestration in reducing a tendency to bleeding was most marked in operations on the spine, then, in turn on the head, neck, chest and abdomen. A favorable influence on the course of the anesthesia was evident in a few but not in all cases. There was no tendency to after-hemorrhage in any instance, but symptoms were observed in a few cases suggesting that the method had better be regarded as contra-indicated in case of pressure on the brain, arteriosclerosis, blood-diseases and varicose veins, on account of danger of thrombosis, but this need not be feared with normal vessels. By applying constriction to the roots of the limbs, it is possible thus to sequestrate a fourth of the total amount of blood (1,300 to 1,500 c.c.). The body reacts to this with a lower blood-pressure and acceleration of pulse and respiration. This sequestration method is particularly advantageous in operations on the brain and spine and when there is reason to dread a parenchymatous hemorrhage. He followed Dawbarn's technic at first but later modified it a little, applying the constriction to both arms and thighs from forty-five to sixty minutes before the operation, and drawing the elastic bands tight enough to arrest the venous blood circulation completely, overcoming the diastolic blood-pressure but respecting the arterial circulation as much as possible. In Bier's constriction hyperemia the constriction has to be only equal to or just

below the diastolic blood-pressure, while Klapp's technic shuts off both the arterial and venous circulation. Zoeppritz' long article discusses the subject from every point of view, including the results of experiments to determine the actual amount of blood that can be thus stored up in the extremities. By-effects were observed only in patients with abnormally high blood-pressure or arteriosclerosis or some blood disease or varicose veins, and these conditions contra-indicate the method principally on account of the danger of inducing anemia in the brain. This applies also to infectious diseases, intoxications, etc., inducing a tendency to vasomotor paralysis.

152. **Operative Treatment of Obstipation.**—Stierlin refers to the cases in which the feces accumulate and stagnate in the cecum and ascending colon and induce the symptoms ascribed to chronic appendicitis, impairing the general health and refractory to all internal measures, and in which roentography locates the stagnation at these points instead of at the sigmoid or other flexures. He excludes the ascending colon by implanting the lower end of the ileum in the transverse colon, resecting the ascending colon or not according to the case, and has done this in ten cases with good end-results in nine; the outcome in the tenth case is not known.

153. **Streptothrix Mycosis of the Lung.**—The case reported by Liek is, he thinks, the first on record in which a serious affection of this kind was arrested and cured by resection of the gangrenous focus. His patient was a man of 44 and the operation was done about five months after the first symptoms had been observed.

156. **Treatment of Retroflexion of Pregnant Uterus.**—Graefe has investigated conditions in regard to the disturbances from this cause in 200 women and found that sixty-one had experienced no local discomfort from this displacement of the uterus. The pregnancy was in the second or fourth month and in two of these patients the uterus was very large, owing to the additional presence of a myoma. These sixty one cases show that retroflexion does not necessarily cause pain or discomfort even when the uterus is unusually large. One patient in this group had had severe sacral pains but after cure of a coincident suppurative catarrh of the cervix and large erosion the pains vanished permanently, although the retroflexion persisted uncorrected. Only seventeen of the total 200 complained of a sensation of downward pressure and only seven of pressure on the rectum. In six of these seven this sensation persisted after the uterus had been restored to place, suggesting that it was purely a nervous phenomenon. None of the patients complained of disturbances in defecation. Only twenty-five of the total 200 complained of traction on the bladder and tenesmus, and these were eight women in the second month, twelve in the third, four in the fourth and one in the fifth month of pregnancy, while thirty-eight other women from two to six months pregnant had no bladder disturbances, not even the two with incarcerated retroflexion. One patient complained of pain radiating to the leg, but it persisted unmodified after the uterus had been restored to place. As a rule disturbances were noted only in women inclined to nervousness or hysteria. Abortion occurred in only thirty-one of the 200 cases, the interval after correction ranging from the first days to four months, and in two of these cases the abortion was criminally induced, while the other women had severe venereal disease. Graefe thinks that the retroflexion alone does not induce abortion but that it has a favoring influence when the uterus is already pathologic. Severe pain and hemorrhage, even slight, indicate at once correction of the retroflexion, as also incarceration of the retroflexed uterus, and in any event he thinks that an attempt should be made to correct the displacement as labor pains and hemorrhage may occur at any moment. A point of great importance in the correction is to keep the bladder empty. Correction succeeds sometimes only with the patient in the knee-elbow position. In some cases the uterus rights itself in a day if the patient lies on her side, or, better yet, in the ventral decubitus in bed. In one incarcerated case the uterus righted itself in six hours after an inflatable bag had been introduced into the vagina and filled with 400 gm. of water. If the adhesions are tough and the patient suffering and all other means fail, a laparotomy becomes necessary although he had to resort to it only in one case. In two cases Goldberg's maneuver accomplished the purpose (described in The Journal, Jan. 21, 1911, page 231).

168. **Influencing of Hypertrophy of the Prostate by Roentgen Exposures of the Testicles.**—Wilms and Posner remark that the gynecologists' discovery that myomas in the uterus can be made to retrogress by exposing the ovaries to the Roentgen rays has suggested that the enlargement of the prostate may be analogous to the development of a myoma, and that it can be indirectly influenced in the same way. The gynecologic experiences suggest that the growth of the myomas is stimulated by some substance generated in the ovaries, and that by reducing the vital action of the ovaries this substance is no longer produced and the myoma withers away. The condition in a hypertrophied prostate is remarkably like that in a myomatous tumor. Zuckerkandl has recently called attention to his finding intact tracts in the prostate when parts of it were much hypertrophied, and that the nodular new growth is essentially in the upper part of the prostate, while the prostate, like the uterus, attains its development with puberty. These and other facts confirm the assumption of a hormone generated in the testicles as responsible for the adenomyomatous nodules developing in the prostate. They suggest that the enlarged prostate can be made to shrivel away to approximately normal size by inducing the retrogression of the testicles, and this can be done in the simplest and most harmless manner by exposing them to the Roentgen rays, as he found in the one case in which he has applied the method to date. The patient was a healthy farmer of 69 and the prostate had gradually become enlarged until retention was complete. The testicles were then exposed to a three-fourths Sabouraud dose of Roentgen rays and four days later there was some spontaneous emission of urine.

By the fifth day the catheter was no longer necessary and micturition soon became entirely normal and the prostate perceptibly smaller, but there was still 70 c.c. of residual urine. A second similar exposure was then made three weeks after the first, since which time conditions in regard to urination have been quite normal and the patient has been in continuously good health.

170. See Abstract 152 above.

173. **Pseudofever in Children.**—Avellis has encountered a number of children apparently healthy but with a rectal temperature above normal for weeks or months at a time. After exclusion of all other causes he compared the rectal with the axilla temperature, and found the latter constantly normal. The conclusion seems inevitable that some local process, possibly merely the vital processes of the intestinal bacteria, may be accepted as the source of this local temperature. In some cases he was able to reduce the temperature to normal by putting the child on a yoghurt or clabber diet; this evidently modified the intestinal flora. He warns that the temperature in these cases is not an evidence of fever and that the children should not be kept in bed. He urges physicians to be on the lookout for this pseudofever and not be misled to ascribe it to tuberculosis, etc.

177. **Neurorecurrences After Salvarsan Treatment, Especially Polyneuritis.**—Trömner and Delbanco report three cases of severe manifestations of so-called neurorecurrence in syphilitics under salvarsan treatment. The first patient was a young man given two intravenous injections of salvarsan in the fourth month after infection, and they were followed two months later by multiple paralysis of cranial nerves. There was total deafness on the left side, with the characteristics of a true syphilitic affection of the auditory nerve on this side, while on the right side the symptoms indicated a toxic injury of the right auditory nerve. In the second case a woman of 28 developed weakness and paralysis in the domains of the first, sixth, seventh, ninth and eleventh cranial nerves two months after an intragluteal injection of salvarsan, and as these phenomena subsided signs of mild polyneuritis became evident. There has been improvement during the six months since, but certain symptoms still indicate meningitic irritation. The case was complicated by a tendency to hysteria. The peripheral polyneuritis in this case and in a third and more severe case are, they think, the first syndromes of the kind observed under salvarsan. It was extremely severe in the third case, developing two months after the injection; the normal pupil reaction and lack of sensory disturbances spoke against tabes. The muscles of the left leg give the reaction of degeneration to electric tests and the reaction was sluggish in the other leg. The patient was a machinist of 33 with no history of syphilis but a positive Wassermann reaction. He suddenly developed crossed hemiparaplegia which gradually improved under mercurial treatment so that he was able to get about on crutches. At his request then an intramuscular injection of 0.3 gm. salvarsan was made. Eight days later the signs of peripheral polyneuritis became evident and persisted with little improvement during the three months since, while only the Babinski and Oppenheim reactions were left of the preceding Brown-Séquard syndrome. Trömner differs from Delbanco in his opinion in regard to the mechanism of these neurorecurrences. He believes that salvarsan is liable to display a direct toxic action with or without the presence of syphilis, and an indirect specific action in syphilis, either by inducing an early inflammatory reaction or by reactivating syphilitic processes during a certain critical period lasting about two months after the injection. That these recurring manifestations are generally in the form of multiple neuritic or perineuritic paralyses of the cranial or, more rarely, of the peripheral nerves is due in part to a special affinity of the drug for nerve tissue. A direct neurotoxic action should be assumed only in the rare cases in which the mischief develops early and runs a malignant course.

Delbanco on the other hand ascribes the neurorecurrences to a direct toxic action on the nerve, and consequently decries the idea of treating them with more of the drug or even with mercury. He wonders what will be the ultimate fate of an auditory nerve, for instance, after toxic injury of this kind, then suffering later from the influence of the syphilis which in turn is arrested by mercury. Will the nerve after these varied experiences be more exposed to injuries later or not? He discusses in detail the literature that has appeared on the subject of neurorecurrences in syphilis since salvarsan has been introduced, and cites from a personal communication from Ehrlich, who was consulted in regard to the polyneuritis cases before the report was published. Delbanco insists that only those cases in which salvarsan has been given alone, without mercury, are strictly demonstrative and suitable for statistical comparison. He adds that the explanation advanced for the neurorecurrences in the auditory nerve, namely, that the natural reaction which otherwise does no harm, causes disturbance here, as the nerve is shut in tight in a narrow bony passage, cannot apply to his cases of peripheral polyneuritis. He adds that the future will teach whether salvarsan exerts an appreciable neurotropic action in nonsyphilitics. The Wassermann reaction is, he thinks, merely a sign that the organism has been in contact with the syphilis germ, and when the diagnosis of syphilis is otherwise clear he does not allow his treatment of syphilis to be guided by the absence or presence of the reaction. The question as to why the salvarsan exerts a toxic action only on certain nerves and not on others cannot be answered any more than why other poisons, especially lead, act on certain groups of muscles and not on others. He admits, however, that the recurrences in syphilis have been subjected to far closer scrutiny since the introduction of salvarsan, but he protests most decidedly against the statement recently made by Benario that in 1 per cent. of all cases of syphilis there is recurrence of symptoms in the large cranial nerves. This cannot be true of cases in which mercurial treatment has been systematically applied.

178. **Nervous Vomiting in Infants.**—Rott refers to the vomiting which resists correction of the diet and for which no cause can be discovered. In this form the vomiting generally starts during the first weeks of the child's life, and it may simulate the clinical picture of pyloric spasm except for the lack of peristalsis in the stomach and of the palpable tumor at the pylorus. He has encountered six cases of this kind during the last two years; in three the vomiting was of an explosive character, immediately after the meal or an hour or so later. Only one of the six infants had reached the fourth month; two were breast-fed and all showed signs of nervous irritability, the children being remarkably restless before the vomiting came on, and the muscles were tense. In four cases an inherited nervous taint was evident. The facts observed suggested that the trouble was a hypersensitive condition of the stomach mucosa due to a congenital nervous irritability. Treatment to reduce this irritability proved remarkably successful in his cases; he gave 10 c.c. of a 0.01 per cent. solution of cocain, that is, 1 mg. of cocain, five times a day, ten minutes before feeding. In three cases the tendency to vomiting completely disappeared within three days; in one case the vomiting recurred on one day after an interval of four days. He gave the cocain for six days regardless of whether the vomiting had ceased, and no by-effects were observed suggesting intoxication, although all the children quieted down. The attempts of others with cocain have failed because it was given with the meals, too late to suppress the irritation from the food. The children have all developed well since, except that some are still unduly nervous. In two other cases the vomiting was not influenced by the cocain; it was never of a spastic character, the stomach content flowing without effort out of the mouth, once a day

or after each meal. The abdomen and muscles were generally flabby and the vomiting seemed to be due to atony, on which the cocain had no effect. One child died; the other grew stronger as the vomiting gradually subsided in the course of a few weeks, but the child developed a tendency to spasmophilia. In two cases of pyloric spasm the cocain was given in the same way and the vomiting became less frequent, the stools normal and the children less restless. These results encourage further trials of cocain with pyloric spasm, possibly combined with other sedatives.

181. **Operative Treatment of Prolapse of the Rectum in Children.**—Sack reviews the nine different methods on record for correction of rectal prolapse in children, with the experiences reported to date. All confirm the superior advantages of the latest technic, that published by Sick in 1909, tamponing the retrorectal space. Ritter has modified it somewhat, and Sack reports the details of two cases in which it has been applied with unusually favorable results, the little patients being able to be up and about at once, defecation not being interfered with and reexamination seven and fourteen months later confirming the advantages of this simple and harmless technic. The only incision is made from the tip of the coccyx to the edge of the sphincter. The loose connective tissue behind the rectum is then separated with a blunt instrument up to the promontory, thus detaching the rear wall of the rectum, and a passage is made entirely around its lower segment. A broad strip of gauze is then worked through this passage to encircle the lower part of the rectum and the ends are brought out, crossed and fastened to the skin above the coccyx. A second gauze strip is pushed up between the rear wall of the rectum and the sacrum. The incision is then sutured except at the top where the ends of the gauze emerge. By this means the rectum is enticed to become broadly adherent to the surrounding tissue and the tendency to prolapse is cured. In both his cases the tampons could be removed the fifth day while the child was allowed to defecate normally from the first, the strip encircling the lower part of the rectum effectually preventing any tendency to prolapse.

182. **The Conjunctival Tuberculin Reaction in Urology.**—Paschkis and Necker state that a further series of 125 urologic cases confirms the conclusions of their first series of orty-two cases, reported in 1908, to the effect that the phthalmo-reaction is one of the numerous diagnostic measures which are instructive in the puzzling cases. They commend the simple technic, declaring that in their experience to date it has been harmless. A negative conjunctival reaction with evident tuberculosis of one kidney, even although its mate is *apparently* functioning normally, is a bad sign. In their four cases of this kind the patients all died in a few months.

194 *The Cerebrospinal Fluid in Tuberculous and Serous Meningitis. (Ergebnisse der Permanganattitration des Liquor cerebrospinalis.) E. Mayerhofer and R. Neubauer.

186. **Lime as Factor in Electric Reaction in Spasmophilia.**—Reiss reports experimental and clinical experiences which sustain the assumption that extreme neuromuscular excitability in children is due in part to lack of *normal proportions* of lime in the tissues. He concludes further that lime is the only one among the cations indispensable for the human organism investigated to date, which influences the electric reactions by its varying concentration. At the same time there must be other factors involved, as the varying lime content does not explain all the phenomena observed, although the theory of a deficiency in lime as the direct cause of the spasmophilic syndrome explains several essential features of it.

191. **Stagnation of Heat and Salt Fever.**—Heim and John report further research on alimentary fever in infants and especially the fever that follows intake of salt. They have become convinced that physical factors predominate in it, the salt causing retention of water and thus interfering with the normal throwing off of heat by means of sweating and urinating. The salt induces retention of water and this in turn induces stagnation of heat.

194. **The Cerebrospinal Fluid in Serous and Tuberculous Meningitis.**—Mayerhofer and Neubauer commend the potassium permanganate method of examination of the cerebrospinal fluid as a rapid and reliable method of investigating the metabolic processes occurring in the central nervous system. The findings are not only instructive for the diagnosis, but throw light on the prognosis. They have examined the fluid in 118 cases, with 182 punctures and 518 separate tests of the fluid. The children had meningitis of various origins, convulsions or poliomyelitis. In all this material the findings in tuberculous meningitis were constantly increased, the increase ranging from 2 to 30 or 37.3. Such high figures were obtained otherwise only in tuberculous pleurisy or peritonitis. At the same time they warn that this alone is not sufficient grounds for assuming a tuberculous meningitis unless confirmed by repeated reexaminations. With meningeal symptoms of *other origin*, the test shows figures under 2 as a rule, and this low figure persists even when the naked-eye aspect of the fluid indicates suppuration. The last series of 100 children examined are reported in detail with the necropsy findings in fifty-two of the fifty-five meningitis cases, and the various methods of examining the cerebrospinal fluid are discussed and the advantages of permanganate titration are extolled. The technic for this test was described in THE JOURNAL, June 11, 1910, p. 2009.

204 Operative Treatment of Tumors in Nasopharynx. (Nasen-Rachengeschwülste.) Z. Slawinski.

203. **Transverse Colon for Plastic Operation on the Esophagus.**—Kelling attempted to relieve a woman of 45 with an inoperable carcinoma in the esophagus by making a new segment out of a strip resected from the transverse colon, suturing one end in the anterior wall of the stomach and connect-

ing the other end with the esophagus above the tumor by an intervening tube formed of the skin of the chest, with a T drain to drain away the saliva. The results of the operation were excellent but the patient succumbed to the effects of the cancer in two weeks. The case teaches that the transverse colon is well adapted for the purpose, and, secondly, that operations of this kind in cases of cancer of the esophagus, seldom offer prospect of success, owing to the ulceration and stagnation in the tumor and the intense reflex salivation. The absorption of toxins from the cancer has an unfavorable action on the secretions of the pancreas, etc., so that the food is not properly assimilated. The results of plastic operations with cancer of the esophagus, therefore, cannot be compared with those with pyloric cancer.

216. **Resistance to Heat of Antibodies Giving the Wassermann Reaction.**—Thomsen and Boas call attention to the fact that the Wassermann reaction occurs regularly with serum from non-syphilitic patients, with cancer, nephritis, scarlet fever, leprosy and tuberculosis, if the serum is not heated, but the syphilitic serum is the only one that gives the reaction after the serum has been heated to 56 C. for half an hour, which is a necessary element in the true Wassermann technic. The heating sifts out all but the true syphilitic cases, the syphilitic serum being the only thermoresisting one. This thermoresisting property is particularly pronounced in inherited syphilis; in the first phase of syphilis the thermoresistance is slight, probably no higher than with cancer, nephritis, etc. The question now is whether this thermoresistance is the property of the antibodies generated or of the medium containing them, but the research reported seems to have established beyond question that these antibodies which give the Wassermann reaction occur regularly in various diseases, while their resistance to application of heat varies within a wide range.

218. **Syphilitic Cardiovascular Disturbance.**—Øigaard reviews his experience with twenty patients of this category, expatiating particularly on the frequently indispensable aid to be obtained from the Wassermann reaction in diagnosis of syphilis of the heart and vessels. There are three principal types of syphilitic affections of the cardiovascular system, aneurysm at the arch of the aorta, aortic insufficiency and syphilitic aortitis. The latter can generally be diagnosed from the clinical picture alone. The Wassermann reaction in all these types is usually very pronounced even when the infection is of twenty to forty years' standing. Treatment was successful only with mercury in his twenty cases, and the results were often surprisingly good, far better than are obtainable by any means with heart disease of other origin. He never witnessed any benefit from iodid in these syphilitic heart and vascular affections. He advises keeping up the mercury until the subjective symptoms have subsided and the Wassermann reaction has become negative after suspension of the treatment for at least three weeks. After the Wassermann reaction has once become negative under treatment, it can no longer be utilized as a guide in treatment—the flaring up of symptoms anew requires renewed specific treatment, regardless of the Wassermann findings. One of his patients with albuminuria (syphilitic nephritis) and intense Wassermann reaction was entirely cured by a three months' course of mercury and iodid. The details of his twenty cases are given in full.

220. **Intoxication from Fibromyoma in the Uterus.**—Kaarsberg has had two patients with fibromyomas in the uterus decaying without suppuration but absorption of necrotic matters caused fever. The growth was seen to increase rapidly in size during two or three weeks, which clinched the necessity for its removal. There were no other symptoms but the fever, no pains nor tenderness. In one case the necrosis was evident only on microscopic examination. In a third case a woman of 70 died after a period of fever suggesting typhoid, but necropsy disclosed no cause for the fever except a central patch of necrosis in a large fibromyoma in the uterus. In other cases a latent necrosis may induce a more chronic intoxication; the temperature may be normal or only slightly above, but the pulse is accelerated and the patient feels weak and cachectic. In the course of four or five months considerable anemia may develop, although without appreciable hemorrhages. Kaarsberg's patient was so weak she swooned twice during the examination. There was a blowing sound at the heart but no purulent or fetid vaginal discharge. The temperature ran up very high a few days before death, having previously been normal; the pulse had been 100. The rise in temperature was accompanied by a purulent discharge from the vagina and the uterus was at once removed but the

or after each meal. The abdomen and muscles were generally flabby and the vomiting seemed to be due to atony, on which the cocain had no effect. One child died; the other grew stronger as the vomiting gradually subsided in the course of a few weeks, but the child developed a tendency to spasmophilia. In two cases of pyloric spasm the cocain was given in the same way and the vomiting became less frequent, the stools normal and the children less restless. These results encourage further trials of cocain with pyloric spasm, possibly combined with other sedatives.

181. **Operative Treatment of Prolapse of the Rectum in Children.**—Sack reviews the nine different methods on record for correction of rectal prolapse in children, with the experiences reported to date. All confirm the superior advantages of the latest technic, that published by Sick in 1909, tamponing the retrorectal space. Ritter has modified it somewhat, and Sack reports the details of two cases in which it has been applied with unusually favorable results, the little patients being able to be up and about at once, defecation not being interfered with and reexamination seven and fourteen months later confirming the advantages of this simple and harmless technic. The only incision is made from the tip of the coccyx to the edge of the sphincter. The loose connective tissue behind the rectum is then separated with a blunt instrument up to the promontory, thus detaching the rear wall of the rectum, and a passage is made entirely around its lower segment. A broad strip of gauze is then worked through this passage to encircle the lower part of the rectum and the ends are brought out, crossed and fastened to the skin above the coccyx. A second gauze strip is pushed up between the rear wall of the rectum and the sacrum. The incision is then sutured except at the top where the ends of the gauze emerge. By this means the rectum is enticed to become broadly adherent to the surrounding tissue and the tendency to prolapse is cured. In both his cases the tampons could be removed the fifth day while the child was allowed to defecate normally from the first, the strip encircling the lower part of the rectum effectually preventing any tendency to prolapse.

184 Traumatic Pseudomeningoceles. J. Winkler.
185 Prostatic Adenoma Removed by Aspiration During Lithotripsy. K. Frank.

182. **The Conjunctival Tuberculin Reaction in Urology.**—Paschkis and Necker state that a further series of 125 urologic cases confirms the conclusions of their first series of forty-two cases, reported in 1908, to the effect that the ophthalmo-reaction is one of the numerous diagnostic measures which are instructive in the puzzling cases. They commend the simple technic, declaring that in their experience to date it has been harmless. A negative conjunctival reaction with evident tuberculosis of one kidney, even although its mate is apparently functioning normally, is a bad sign. In their four cases of this kind the patients all died in a few months.

194 *The Cerebrospinal Fluid in Tuberculous and Serous Meningitis. (Ergebnisse der Permanganattitration des Liquor cerebrospinalis.) E. Mayerhofer and R. Neubauer.

186. **Lime as Factor in Electric Reaction in Spasmophilia.**—Reiss reports experimental and clinical experiences which sustain the assumption that extreme neuromuscular excitability in children is due in part to lack of normal proportions of lime in the tissues. He concludes further that lime is the only one among the cations indispensable for the human organism investigated to date, which influences the electric reactions by its varying concentration. At the same time there must be other factors involved, as the varying lime content does not explain all the phenomena observed, although the theory of a deficiency in lime as the direct cause of the spasmophilic syndrome explains several essential features of it.

191. **Stagnation of Heat and Salt Fever.**—Heim and John report further research on alimentary fever in infants and especially the fever that follows intake of salt. They have become convinced that physical factors predominate in it, the salt causing retention of water and thus interfering with the normal throwing off of heat by means of sweating and urinating. The salt induces retention of water and this in turn induces stagnation of heat.

194. **The Cerebrospinal Fluid in Serous and Tuberculous Meningitis.**—Mayerhofer and Neubauer commend the potassium permanganate method of examination of the cerebrospinal fluid as a rapid and reliable method of investigating the metabolic processes occurring in the central nervous system. The findings are not only instructive for the diagnosis, but throw light on the prognosis. They have examined the fluid in 118 cases, with 182 punctures and 518 separate tests of the fluid. The children had meningitis of various origins, convulsions or poliomyelitis. In all this material the findings in tuberculous meningitis were constantly increased, the increase ranging from 2 to 30 or 37.3. Such high figures were obtained otherwise only in tuberculous pleurisy or peritonitis. At the same time they warn that this alone is not sufficient grounds for assuming a tuberculous meningitis unless confirmed by repeated reexaminations. With meningeal symptoms of other origin, the test shows figures under 2 as a rule, and this low figure persists even when the naked-eye aspect of the fluid indicates suppuration. The last series of 100 children examined are reported in detail with the necropsy findings in fifty-two of the fifty-five meningitis cases, and the various methods of examining the cerebrospinal fluid are discussed and the advantages of permanganate titration are extolled. The technic for this test was described in The Journal, June 11, 1910, p. 2009.

204 Operative Treatment of Tumors in Nasopharynx. (Nasen-Rachengeschwülste.) Z. Slawinski.

203. **Transverse Colon for Plastic Operation on the Esophagus.**—Kelling attempted to relieve a woman of 45 with an inoperable carcinoma in the esophagus by making a new segment out of a strip resected from the transverse colon, suturing one end in the anterior wall of the stomach and connect-

ing the other end with the esophagus above the tumor by an intervening tube formed of the skin of the chest, with a T drain to drain away the saliva. The results of the operation were excellent but the patient succumbed to the effects of the cancer in two weeks. The case teaches that the transverse colon is well adapted for the purpose, and, secondly, that operations of this kind in cases of cancer of the esophagus, seldom offer prospect of success, owing to the ulceration and stagnation in the tumor and the intense reflex salivation. The absorption of toxins from the cancer has an unfavorable action on the secretions of the pancreas, etc., so that the food is not properly assimilated. The results of plastic operations with cancer of the esophagus, therefore, cannot be compared with those with pyloric cancer.

206 *Pregnancy and Delivery in Tabes Dorsalis. Jakub.
207 Premonitory Symptoms of Thrombosis and Embolism. H. Michaelis.

205. Gynecologic Prophylaxis of Suicidal Mania.—Bossi's experience with the cure of a tendency to melancholia and mania by correction of abnormal conditions in the genitalia was summarized in THE JOURNAL, September 30, page 1173, abstract 165. He urges here the especial importance of the task of gynecologists in a sound prophylaxis against suicide.

206. Pregnancy in Tabetic Women.—Jakub reports the course of pregnancy and delivery in a woman of 36 infected with syphilis at 28 and with signs of tabes dorsalis during the last seven years. This experience confirms the privilege of tabetics over normal women, in that delivery proceeds rapidly and entirely painlessly. The entire childbirth is analogous to what is observed in animals after artificial destruction of the spinal cord; it confirms anew the admirable autonomous nervous apparatus of the uterus which enables it to carry the fetus to term and expel it at the proper time automatically.

216. Resistance to Heat of Antibodies Giving the Wassermann Reaction.—Thomsen and Boas call attention to the fact that the Wassermann reaction occurs regularly with serum from non-syphilitic patients, with cancer, nephritis, scarlet fever, leprosy and tuberculosis, if the serum is not heated, but the syphilitic serum is the only one that gives the reaction after the serum has been heated to 56 C. for half an hour, which is a necessary element in the true Wassermann technic. The heating sifts out all but the true syphilitic cases, the syphilitic serum being the only thermoresisting one. This thermoresisting property is particularly pronounced in inherited syphilis; in the first phase of syphilis the thermoresistance is slight, probably no higher than with cancer, nephritis, etc. The question now is whether this thermoresistance is the property of the antibodies generated or of the medium containing them, but the research reported seems to have established beyond question that these antibodies which give the Wassermann reaction occur regularly in various diseases, while their resistance to application of heat varies within a wide range.

218. Syphilitic Cardiovascular Disturbance.—Øigaard reviews his experience with twenty patients of this category, expatiating particularly on the frequently indispensable aid to be obtained from the Wassermann reaction in diagnosis of syphilis of the heart and vessels. There are three principal types of syphilitic affections of the cardiovascular system, aneurysm at the arch of the aorta, aortic insufficiency and syphilitic aortitis. The latter can generally be diagnosed from the clinical picture alone. The Wassermann reaction in all these types is usually very pronounced even when the infection is of twenty to forty years' standing. Treatment was successful only with mercury in his twenty cases, and the results were often surprisingly good, far better than are obtainable by any means with heart disease of other origin. He never witnessed any benefit from iodid in these syphilitic heart and vascular affections. He advises keeping up the mercury until the subjective symptoms have subsided and the Wassermann reaction has become negative after suspension of the treatment for at least three weeks. After the Wassermann reaction has once become negative under treatment, it can no longer be utilized as a guide in treatment—the flaring up of symptoms anew requires renewed specific treatment, regardless of the Wassermann findings. One of his patients with albuminuria (syphilitic nephritis) and intense Wassermann reaction was entirely cured by a three months' course of mercury and iodid. The details of his twenty cases are given in full.

220. Intoxication from Fibromyoma in the Uterus.—Kaarsberg has had two patients with fibromyomas in the uterus decaying without suppuration but absorption of necrotic matters caused fever. The growth was seen to increase rapidly in size during two or three weeks, which clinched the necessity for its removal. There were no other symptoms but the fever, no pains nor tenderness. In one case the necrosis was evident only on microscopic examination. In a third case a woman of 70 died after a period of fever suggesting typhoid, but necropsy disclosed no cause for the fever except a central patch of necrosis in a large fibromyoma in the uterus. In other cases a latent necrosis may induce a more chronic intoxication; the temperature may be normal or only slightly above, but the pulse is accelerated and the patient feels weak and cachectic. In the course of four or five months considerable anemia may develop, although without appreciable hemorrhages. Kaarsberg's patient was so weak she swooned twice during the examination. There was a blowing sound at the heart but no purulent or fetid vaginal discharge. The temperature ran up very high a few days before death, having previously been normal; the pulse had been 100. The rise in temperature was accompanied by a purulent discharge from the vagina and the uterus was at once removed but the

or after each meal. The abdomen and muscles were generally flabby and the vomiting seemed to be due to atony, on which the cocain had no effect. One child died; the other grew stronger as the vomiting gradually subsided in the course of a few weeks, but the child developed a tendency to spasmophilia. In two cases of pyloric spasm the cocain was given in the same way and the vomiting became less frequent, the stools normal and the children less restless. These results encourage further trials of cocain with pyloric spasm, possibly combined with other sedatives.

181. **Operative Treatment of Prolapse of the Rectum in Children.**—Sack reviews the nine different methods on record for correction of rectal prolapse in children, with the experiences reported to date. All confirm the superior advantages of the latest technic, that published by Sick in 1909, tamponing the retrorectal space. Ritter has modified it somewhat, and Sack reports the details of two cases in which it has been applied with unusually favorable results, the little patients being able to be up and about at once, defecation not being interfered with and reexamination seven and fourteen months later confirming the advantages of this simple and harmless technic. The only incision is made from the tip of the coccyx to the edge of the sphincter. The loose connective tissue behind the rectum is then separated with a blunt instrument up to the promontory, thus detaching the rear wall of the rectum, and a passage is made entirely around its lower segment. A broad strip of gauze is then worked through this passage to encircle the lower part of the rectum and the ends are brought out, crossed and fastened to the skin above the coccyx. A second gauze strip is pushed up between the rear wall of the rectum and the sacrum. The incision is then sutured except at the top where the ends of the gauze emerge. By this means the rectum is enticed to become broadly adherent to the surrounding tissue and the tendency to prolapse is cured. In both his cases the tampons could be removed the fifth day while the child was allowed to defecate normally from the first, the strip encircling the lower part of the rectum effectually preventing any tendency to prolapse.

206 *Pregnancy and Delivery in Tabes Dorsalis. Jakub.
207 Premonitory Symptoms of Thrombosis and Embolism. H. Michaelis.

205. **Gynecologic Prophylaxis of Suicidal Mania.**—Bossi's experience with the cure of a tendency to melancholia and mania by correction of abnormal conditions in the genitalia was summarized in THE JOURNAL, September 30, page 1173, abstract 165. He urges here the especial importance of the task of gynecologists in a sound prophylaxis against suicide.

206. **Pregnancy in Tabetic Women.**—Jakub reports the course of pregnancy and delivery in a woman of 36 infected with syphilis at 28 and with signs of tabes dorsalis during the last seven years. This experience confirms the privilege of tabetics over normal women, in that delivery proceeds rapidly and entirely painlessly. The entire childbirth is analogous to what is observed in animals after artificial destruction of the spinal cord; it confirms anew the admirable autonomous nervous apparatus of the uterus which enables it to carry the fetus to term and expel it at the proper time automatically.

Gazzetta degli Ospedali e delle Cliniche, Milan

August 31, XXXII, No. 105, pp. 1107-1114

208 *Abdomen Retraction with Gastric Cancer Free from Metastasis. (Del segno di Tansini per la diagnosi di metastasi intestinale nel cancro del piloro.) S. d'Este.

September 3, No. 106, pp. 1115-1130

209 Perforating Ulcer of the Foot. (Sul mal perforante plantare.) G. Tomaselli.

September 5, No. 107, pp. 1131-1138

210 Carbolized Glycerin in Local Treatment of Erysipelas. M. Lodi.

September 7, No. 108, pp. 1139-1146

211 Banti's Disease. F. Piria.

208. **Depression of the Abdomen with Cancer of the Pylorus and Bulging When There is Metastasis.**—Este reports a third case in which Tansini's sign was present and threw light on the condition. In all his experience with cancer at the pylorus or cicatricial stenosis he always found the abdomen drawn in except in those cases in which operation revealed cancerous nodules at some point in the intestines.

222 Anilin Stains in Tests for Bile Pigments in the Urine. (Om Anvendeligheden af Anilinfarver som Reagens paa Galdefarvestof i Urinen.) O. V. Petersen.

216. **Resistance to Heat of Antibodies Giving the Wassermann Reaction.**—Thomsen and Boas call attention to the fact that the Wassermann reaction occurs regularly with serum from non-syphilitic patients, with cancer, nephritis, scarlet fever, leprosy and tuberculosis, if the serum is not heated, but the syphilitic serum is the only one that gives the reaction after the serum has been heated to 56 C. for half an hour, which is a necessary element in the true Wassermann technic. The heating sifts out all but the true syphilitic cases, the syphilitic serum being the only thermoresisting one. This thermoresisting property is particularly pronounced in inherited syphilis; in the first phase of syphilis the thermoresistance is slight, probably no higher than with cancer, nephritis, etc. The question now is whether this thermoresistance is the property of the antibodies generated or of the medium containing them, but the research reported seems to have established beyond question that these antibodies which give the Wassermann reaction occur regularly in various diseases, while their resistance to application of heat varies within a wide range.

218. **Syphilitic Cardiovascular Disturbance.**—Øigaard reviews his experience with twenty patients of this category, expatiating particularly on the frequently indispensable aid to be obtained from the Wassermann reaction in diagnosis of syphilis of the heart and vessels. There are three principal types of syphilitic affections of the cardiovascular system, aneurysm at the arch of the aorta, aortic insufficiency and syphilitic aortitis. The latter can generally be diagnosed from the clinical picture alone. The Wassermann reaction in all these types is usually very pronounced even when the infection is of twenty to forty years' standing. Treatment was successful only with mercury in his twenty cases, and the results were often surprisingly good, far better than are obtainable by any means with heart disease of other origin. He never witnessed any benefit from iodid in these syphilitic heart and vascular affections. He advises keeping up the mercury until the subjective symptoms have subsided and the Wassermann reaction has become negative after suspension of the treatment for at least three weeks. After the Wassermann reaction has once become negative under treatment, it can no longer be utilized as a guide in treatment—the flaring up of symptoms anew requires renewed specific treatment, regardless of the Wassermann findings. One of his patients with albuminuria (syphilitic nephritis) and intense Wassermann reaction was entirely cured by a three months' course of mercury and iodid. The details of his twenty cases are given in full.

220. **Intoxication from Fibromyoma in the Uterus.**—Kaarsberg has had two patients with fibromyomas in the uterus decaying without suppuration but absorption of necrotic matters caused fever. The growth was seen to increase rapidly in size during two or three weeks, which clinched the necessity for its removal. There were no other symptoms but the fever, no pains nor tenderness. In one case the necrosis was evident only on microscopic examination. In a third case a woman of 70 died after a period of fever suggesting typhoid, but necropsy disclosed no cause for the fever except a central patch of necrosis in a large fibromyoma in the uterus. In other cases a latent necrosis may induce a more chronic intoxication; the temperature may be normal or only slightly above, but the pulse is accelerated and the patient feels weak and cachectic. In the course of four or five months considerable anemia may develop, although without appreciable hemorrhages. Kaarsberg's patient was so weak she swooned twice during the examination. There was a blowing sound at the heart but no purulent or fetid vaginal discharge. The temperature ran up very high a few days before death, having previously been normal; the pulse had been 100. The rise in temperature was accompanied by a purulent discharge from the vagina and the uterus was at once removed but the

patient died the next day. Parenchymatous degeneration of the organs was evident, especially of the myocardium. In a fourth case the symptoms and course were exactly the same but the fibromyoma in the uterus was not decaying, no trace of necrosis could be detected even with the microscope. The case demonstrates that a fibromyoma even without necrosis is liable to induce intoxication and degeneration of the myocardium. In a fifth case no operation was attempted and the patient died after four or five months of chronic debility and hemorrhages from a fibromyoma in the uterus. In this case also degeneration of the myocardium was the direct cause of death. This assumption that a uterine fibromyoma —even without necrosis—may induce chronic intoxication is sustained by the way in which such patients improve rapidly in health after removal of the growth. He urges the necessity for keeping an oversight of patients suspected to have these growths and increasing weakness, especially on the part of the heart. The detailed case histories are appended.

Hygiea, Stockholm

August, LXXIII, No. 8, pp. 913-1024

223 *Weight of a Drop. (Om droppvikt.) K. Ahlberg.
224 *Resection of Stomach for Cancer; Operative Mortality and End-Results. J. Waldenström.

223. **Weight of a Drop.**—Ahlberg discusses the inaccuracies that are liable unless the exact weight of the drop of different fluids is known, and he gives a series of tables showing the exact weight in turn of twenty, thirty, forty to eighty drops of a number of common tinctures, extracts, acids, etc., and in another series the number of drops to a gram. The number ranges from twenty to sixty drops to the gram, tincture of digitalis having fifty, fluid extract of ergot thirty, tincture of opium forty, and the 1 to 1,000 epinephrin solution only twenty according to his experience.

224. **Resection of the Stomach for Cancer.**—Waldenström compares the statistics from some leading German, Swiss American and Swedish clinics, showing that Mikulicz had the highest percentage of survivors for more than three years after resection of the stomach for malignant disease, his figure being 30 per cent., or 39 per cent., if only the last three years of his work are included. Waldenström gives the details of the fourteen cases in which the patients have been free from recurrence for more than three years since the operation done at the Serafimer Hospital at Stockholm, out of a total of ninety-three patients thus operated on between 1888 and 1907. He urges efforts to convince patients of the advisability of a harmless exploratory laparotomy when there are symptoms of chronic dyspepsia and deficient gastric secretion while the patients are losing weight. Cooperation between the internist and the surgeon seems to be the only way to realize further progress in treatment of gastric cancer. In the successful cases reported from the Serafimer, the first symptoms had been noticed from two months to eight years before operative treatment was applied.

THE TREATMENT OF THE ARTHRITIDES *

L. LITCHFIELD, M.D.
PITTSBURGH

It is natural that diseases the most obvious features of which are located in the joints should be grouped together just as diseases of the meninges, lungs, gastro-intestinal tract, etc., are grouped. While we recognize the basis of classification in the other classes and realize that the diseases may have nothing in common, except the localization of some of their phenomena, in the case of the joints we have not yet progressed so far. No class of cases seems to offer greater facilities for study and treatment, and yet in the mind of the average practitioner everything, except the typical cases of rheumatic fever, is thrown into a nebulous class of chronic, rheumatic, rheumatoid or gouty arthritis, the treatment of which is almost hopelessly chaotic. Since Sydenham differentiated acute rheumatic fever from gout, little progress has been made, speaking for the profession at large.

This confusion of ideas with the consequent therapeutic failures is the natural result of certain conditions of which I shall consider the three most important:

1. The unfortunate persistence and extension of the term rheumatism without any definite significance. The permutations and combinations of this term "rheumatism" have contributed so much to misunderstanding, to lack of precision in diagnosis, and consequent lack of definite aim in treatment, to confusion of diseases and confusion of ideas as to the cause, relationship, and management of diseases that it would be far better to drop the term altogether, using the name "rheumatic fever" instead, and ringing no changes on that term, like rheumatoid, gonorrheal rheumatism, rheumatic affections, etc.

2. The flooding of medical literature year after year, under authoritative names, with obsolete, misleading, and unnecessarily confusing statements merely because they are traditional and because the publishers must have filling for their new books. If writers would boldly leave the legendary and condense their writing to what is known, our horizon would soon be much clearer and our book-shelves less congested with crops in which the tares outweigh the corn. One can only vaguely imagine the time that would be saved.

I have long been of the opinion that this evil is largely the result of the energy and enterprise of our medical publishing houses. Where we need one publishing house, we have six or eight. All must keep busy continuously or they will lose money. Therefore, they must coerce the medical profession into writing and buying this unnecessary mass of stuff. If one publisher gets out a book on therapeutics, immediately the others try to duplicate it and we get possibly three or four thousand pages of the printer's art, when two or three hundred pages would give all that is new and worth reading.

3. The paucity of our knowledge as to the etiology of the pathologic conditions observed in the joints. But do the current works on diagnosis, dietetics, and treatment adequately reflect the present state of our knowledge regarding these subjects? Let us consider for a few moments this important question. I assume that the following definite facts and principles may be regarded as established or at least as accepted by investigators as working hypotheses. Exclusive of trophic, hemophilic, traumatic and certain septic cases, the arthritides may be divided into three classes—rheumatic fever, gout, and hypotrophic and hypertrophic arthritis.

1. As to the nature of gout, this disease is due to the abnormal accumulation of uric acid in the system, resulting from its increased production, diminished destruction, or faulty elimination; to the change of the monosodium urate circulating in the organism, from a soluble to a less soluble isomeric form, and its precipitation in the tissues.[1] This uric acid is no longer regarded as a stage in the production of urea, but as a natural end product of purin metabolism, resulting about equally from endogenous and exogenous sources. Consequently, the amount of uric acid to be disposed of may be cut down 50 per cent. by a purin-free diet. I think it is safe to say that nothing in dietetics is so well established as the indication for a purin-free diet in gout. This indication is even more exacting than that for a low carbohydrate diet in diabetes mellitus. For we must try as far as possible to increase the tolerance for carbohydrates in diabetes, but there is no such pressing therapeutic reason for trying to increase the tolerance for the purin bodies in gout.

2. The fact that what is designated as "rheumatic fever" or often as "acute rheumatism," "polyarticular rheumatism," or just "rheumatism" is a general infection, whether we regard the so-called *Streptococcus rheumaticus* of Poynton and Paine as the cause or as an attendant phenomenon like the streptococcus blood-infection in most cases of scarlet fever[2] and many cases of measles[3] and small-pox.[4]

3. The disease or diseases commonly called arthritis deformans and rheumatoid arthritis or hypertrophic and hypotrophic arthritis—whether we regard these two very different pictures as different manifestations of the same, or as two distinct diseases—are not closely related etiologically either to gout or to rheumatic fever.

---

* Chairman's address before the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Gudzent: Ztschr. f. physiol. Chem., lv, 38; Therap. d. Gegenw., December, 1910; Med. Klin., 1909, No. 37.

[2] Moser: Brit. Med. Jour., Oct. 4, 1902.

[3] Cornil and Babes: Traité de méd., ii, 84; Garre: Fortschr. d. Med., 1885, p. 165; Councilman: Jour. Med. Res., 1904, p. 1.

[4] Park: Pathogenic Bacteria and Protozoa, 1890, p. 484.

4. The only agent that has been scientifically proved to increase materially the elimination of uric acid without correspondingly increasing its production is radio-activity.

5. Excess of sodium in the tissues predisposes to gouty deposit of sodium urate, and therefore in the so-called gouty diathesis the administration of hydrochloric acid is more logical than the alkaline treatment.

6. Doubtful or atypical cases of gout can be diagnosed only by scientifically testing the capacity of the organism to eliminate uric acid or by the demonstration of the presence of uric acid in the circulating blood, the latter being of value in rare cases only.

7. There is no such thing as an antirheumatic diet and all patients suffering from chronic arthritis, except the gouty, should be as generously nourished as their digestive capacity will permit.

8. Many cases of arthritis are unfavorably influenced by septic foci, as pyorrhea, infected tonsils, antra, frontal sinuses, ethmoid or sphenoid cells, prostate, etc. In certain cases these foci may be ports of entry of the disease germs or sources of the toxins which cause the irritation in the joints.

With the facts just given, let us contrast the following extracts from some of the latest and most popular books of reference, by which many of us shape our daily management of cases. In a reference system published within ten years, an imposing article on dietetics prescribes the same diet for chronic rheumatism, gout and *various skin affections*. In one of the latest and most popular systems published in England during the last three years appears a very good article on gout, but there is *no mention* of purin metabolism in its relation to gout, and no mention of radio-activity; diet tables which are worse than useless are included.

In a "thoroughly revised" edition of a standard work on dietetics published within three years, we read under "gout": "Take moderate quantities of plain nutritious food, avoid excess of meat, and all rich food, and eat only moderate quantities of starches and sugars." This is advice better adapted to almost any other condition than to gout. Then follow detailed directions for all kinds of meats, meat soups, etc., with a caution as to eggs, and an injunction against dried beans or peas, sweet potatoes, beets, ice-cream and cheese, all of which are really harmless in gout, as compared with meat and meat soups, which the author allows.

In another recent system on therapeutics we read under "hydrotherapy" that in the treatment of gout and rheumatism by baths it is simply a question of temperature, duration and pressure (no mention of radio-activity), and further that in all cases of "rheumatic" and "gouty" character the patients should be subjected to hydrotherapy early, medication being practically useless except as a palliative. It is exceedingly common to find these words "rheumatic" and "gouty" linked together, and it adds greatly to the existing confusion.

In the same system we find in an article on "Diet in Gout" a glimmering suggestion as to the relation of purin bodies to uric acid, but this idea is not carried out in the diet tables which follow. In a paragraph on "rheumatic headache" the writer says that this may be (1) "a simple localized affection" or (2) due to "lithemic toxemia, an auto-intoxication from the disturbed gastro-intestinal tract," or (3) to congestion of the tonsils and pharynx. "The local condition may be the result of exposure to cold, sudden checking of the perspiration or the gradual accumulation of the so-called 'rheumatic poison' in the system, from lack of exercise, overfeeding and the use of alcohol." The author then recommends salicylates, colchicum and the iodids — a meaningless jumble of words followed by a shotgun prescription.

In one of the most popular new systems a writer says that there are three varieties of joint affections in typhoid fever, i. e., rheumatic, septic and typhoid proper! and this brilliant classification has been copied year after year by one hurried writer after another. A celebrated English authority contributing to this same system says: "Gout and rheumatism are two diseases which are usually attributed to imperfect tissue metabolism, although there is a tendency, in the case of rheumatism at least, to transfer this disease to the class of infectious diseases." He goes on to sanction the use of alkalies in both cases as favoring the action of oxidases and raising the bactericidal power of the blood. He does not distinguish between the use of salicylates in gout and in rheumatism, saying that they increase the solubility of uric acid. He favors, for reasons which are not given, the use of piperidin, piperazin, etc. Later the same author says: "In cases of disease of the nerve trunks, the treatment resolves itself into the use of electricity and the administration of remedies intended to counteract rheumatic or gouty tendencies, such as alkalies, potassium iodid, salicylates, antipyrin, phenacetin, aspirin, guaiacol, etc."

The one thing which has proved to be of any scientific value in gout is not mentioned in these two large volumes. Such writing shows the same scattering footlessness and rambling lack of scientific foundation as the second-rate proprietary literature with which our offices are flooded; and this stuff is sold to students and practitioners under the authoritative names of men who know better. Should men allow articles which they have never read to be sold as edited by them? Can it be imagined that the alleged editors read these bulky volumes? Is it any wonder that chaos exists in the minds of the profession when our idols are selling us advice which they themselves have never read? Another evil of these pot-boiling "systems" is that they are full of contradictions, no attempt being made by the editors to see that the various authoritative contributions should not flatly contradict one another and leave their readers in the air. Such a collection does not make a system — it is merely a job-lot of *medical articles*.

If a man reads a monograph he chooses a writer in whom he has some confidence or of whom he knows something. When a man buys a system he is influenced by the names of the editors. He has a right to feel that what he reads *in the said system* has the sanction of the editors. In the majority of cases he does not even notice who has written the particular article to which he turns for help in time of need. It is time that those who have deservedly won positions of authority give more careful consideration to that which is going to be sold under their names.

Now, to come back to our classification, I wish to refer particularly to certain points in the treatment of these conditions.

RHEUMATIC FEVER

There is abundant clinical evidence that salicylic acid is *specific* for rheumatic fever and for that disease only. I could cite Kraus of Berlin, Rolleston of England, and many others in support of this opinion. As with other chemical remedies, the treatment should be so managed as to overwhelm the disease as soon as possible and not by small doses long drawn out create a tolerance of the disease-producing organisms for the remedy and at the same time an intolerance of the patient's stomach. Professor Kraus gives 0.5 gm. of salicylic acid hourly day and night until improvement begins, sometimes even to thirty-six hours. The heart and urine should be carefully watched and the treatment should be changed if cardiac depression or albumin and casts are recognized. Following Kraus, I have used some recent synthetics for the past two years whenever the least irritating form of salicylic acid was indicated, and I have been well satisfied with the results.

The combination of alkalies with the salicylic acid treatment of rheumatic fever receives much support from statistics and theoretically at least there are no contra-indications. It is also said to protect the kidneys from the irritating effects of salicylic acid.

The use of vaccines in cases of rheumatic fever as well as in cases of gonorrheal arthritis has been favorably reported on too often to be ignored. Personally, I have had very satisfactory results in both diseases.

In Pittsburgh Drs. Ernest W. Willetts and W. R. S. Denner have cultivated four strains of streptococcus, believed to be identical with that described by Poynton and Paine. Three of these cultures were obtained from blood of patients with acute rheumatic fever and endocarditis. These could not have been terminal infections, as all recovered. One was a culture from the pericardium of a subject who died of chorea with pancarditis. About twenty-five patients have been treated with vaccines made from these cultures, with very satisfactory results. The twenty-five cases include acute and chronic rheumatic fever, chorea, and rheumatic iritis and iridocyclitis. The only patients not benefited were those in whose cases the diagnosis was doubtful.

At all stages of the disease the diet in rheumatic fever should be the most nutritious that the patient can take care of.

CHRONIC HYPOTROPHIC AND HYPERTROPHIC ARTHRITIS

The toxic and septic cases referred to above are most commonly called rheumatoid arthritis (following the English) and arthritis deformans. The diagnosis of the acute manifestations of these two types of disease is sometimes difficult or even impossible in the present state of our knowledge. As to their treatment, possible source of infection should be sought for and removed, though I must say that I have never seen the brilliant results follow the removal of these septic foci that have been reported by others. Still I have several times seen acute exacerbations of the joint affections immediately follow operations on tonsils, antra and appendix. Whether these joints should be exercised or not may sometimes be determined by a study of their radiograms.

The most important point which is not sufficiently recognized is that the patients should be treated along the lines of any chronic infection, that is, by the greatest possible amount of food and outdoor living and sufficient rest to insure the building up of the reserve forces. Many of these patients are very anemic and iron and arsenic are indicated. Care should be taken, if iron is needed, to give enough and to give it in the best form. Shirokauer's recent exhaustive, interesting and instructive article[5] on the use of iron may be referred to here. There is considerable evidence in favor of the use of fibrolysin in certain of these cases to increase the mobility of the joints where the loss of motion is not due to bony changes.[6]

As will be seen later, a certain proportion of these patients have been greatly benefited by treatment with radium emanations.

GOUT

Gout is probably far more common in the United States than is generally supposed. For some reason, not yet explained, the typical cases are relatively infrequent, but I believe that a very large number of atypical cases are overlooked. Although the positive diagnosis of these atypical cases can only be made by testing the purin metabolism or by finding uric acid in the blood (and according to His[7] and Magnus-Levy[8] the former test is sometimes negative in undoubted cases of gout), still a careful consideration of the family history, the patient's previous history and the existing conditions will usually give us sufficient indications for a tentative use of gouty remedies.

The value of colchicum to control the acute symptoms of gout is too well known to require comment.

As regards the influence of alkalies and acids in gouty conditions, there have been a series of very interesting reports which seem to demonstrate that alkalies, particularly sodium,[9] diminish the solubility of uric acid in the blood, and that the administration of hydrochloric acid seems in some way to diminish the alkalinity of the blood, rendering it thereby more disposed to take up the sodium from synovial fluids, etc., where its presence favors gouty deposits. The stronger affinity of hydrochloric acid for sodium prevents the latter from uniting with uric acid.[9] The most interesting articles along this line have been by Falkenstein,[10] Brugsch,[11] van Loghem and Cohn.[9] The practical deduction from the foregoing is the limitation by gouty patients of the ingestion of such vegetables as are high in sodium, and the administration of dilute hydrochloric acid in water or lemonade.

One of the most progressively interesting lines of metabolic work during the past few years has been the development of our knowledge of the therapeutic effects of radium. This subject has received very little notice in America, but for the past two years the German journals have been fairly teeming with it. The reports of forty investigators might be cited from the German medical journals. The British medical press is beginning to notice with enthusiastic approval this German activity.[12] During the past two years there have been seventeen references to radium in British medical literature, eight in the United States, four in Canada, and one in Australia. Most of the notices outside of Germany have been abstracts of or comments on the German work. At the thirty-second Balneologic Congress held in Berlin in March, 1911, one whole session was given to the consideration of the therapeutic effects of radium.[13]

When radio-activity was discovered in the waters of various popular springs, it was at once suspected that this radio-activity might be the essential therapeutic

feature of the springs. Roughly speaking, it was noticed that the springs which seemed to have been the most successful in the treatment of gouty conditions were those which showed the highest radio-activity. Artificially prepared radio-active waters were then experimented with and seemed to show the same therapeutic effects. Animal experiments (His,[7] Kionka,[14] Cohn,[9] Fofanoff[15]) were then undertaken with radium, with the result of demonstrating that the action of radium, therapeutically used, is elective, affecting most the embryonic tissue (the ectodermal tissue), the pathologic tissue of tumors, etc.; that it attacks foreign bodies such as uric acid which has been artificially introduced under the skin or in the peritoneal cavity; that it modifies the phenomena of inflammation and stimulates the action of various ferments as the pancreatic, peptic and lactic acid, and the autolytic ferment in the tissues.[16]

From experiments on man, it was found that radium emanations have no action on the glycolytic ferment in diabetic cases, and no action on the elimination of purin bodies in normal cases, but an accelerating effect on the elimination of purin bodies in gouty cases in which the elimination is delayed. It prevents the rapid change of urates circulating in the organism from a more soluble to a less soluble isomeric form and even reverses that change.[1, 15] It increases the elimination of uric acid as well as its destruction into ammonia and carbonic acid.[1] It increases the general metabolism.[17] It increases the chemotaxic and phagocytic properties of the white blood-corpuscles (Fofanoff). At the various cures, the radium emanations find their way into the organism by inhalation, by penetration through the skin, or by the drinking of the radio-active water, and much has been written as to the relative merits of these different methods.[18, 19]

The most recent method of using radium in these cases was proposed and developed by Felix Mendel[20] of Essen. It consists in the intramuscular injection of a radio-active liquid of standardized strength. By this method Mendel has obtained very definite results in [illegible] of gout, also in certain cases of chronic arthritis. [illegible] seems to confirm the statement of Minkowski, in his work on gout, that there is a close relationship between gout and certain cases of chronic atrophic and hypertrophic arthritis.

Of the many clinical reports of the application of radium to cases of arthritis, and to the so-called gouty diathesis, His[7] has given us the largest series of cases, including twenty-eight cases of gout and one hundred cases of chronic arthritis. Of the twenty-eight cases of gout, four were not improved, twenty-four were considerably improved, several without return of symptoms for one year up to the time of writing. Many of these patients had tried severe dietetic and other measures without benefit, and three patients had been on rigid purin-free diet for some time without benefit until the radium treatment was begun. His observed the disappearance of tophi in two cases, and some cases were clinically much improved, although uric acid persisted in the blood, while rare cases showed many tophi with repeated gouty attacks and no uric acid could be demonstrated in the blood. Of the one hundred cases of chronic arthritis, forty-seven were improved, twenty-nine much improved, five almost cured, thirteen showed no change that could be attributed to the treatment, and six cases could not be followed. The best results were in the more acute or earlier cases, especially in young subjects. Gudzent,[1] Brugsch,[11] Strasburger,[21] Mendel,[20] Fürstenberg and Klemperer,[22] and Kemen,[23] have all recorded similar results.

In this brief reference to the effects of radium on certain pathologic conditions, enough has been said to show the desirability of having an official investigation and standardization of the most important American springs in regard to their radio-activity, and I should be very glad to see a recommendation to this end from this Section to the House of Delegates.

EXPERIMENTAL INTESTINAL OBSTRUCTION

REPORT OF FURTHER PHYSIOLOGIC, CYTOLOGIC AND CHEMICAL STUDIES *

JOHN WILLIAM DRAPER, M.D.§

ROCHESTER, MINN.

In general, those things which we see in mass are most certain to fix attention. The mucous lining of the dog's small intestine spread over 3 meters of tubular surface is more apt to be thought of in microscopic than in macroscopic terms. Possibly this is why certain of its functions relating to the animal economy may have been overlooked. Yet, in weight and, as some believe, in metabolic importance of secretions, it is the analogue of other great glands of the body. Its weight ratio to the thyroid is about as 7 to 1, and to the pancreas as 3 to 4. Its part in the balancing of metabolism has been overshadowed by its more obvious though measurably less important digestive function. It differs from other glands, not alone in its tesselated length, but in having a less free vascular interchange throughout its long course. What peculiar conditions as to function do these morphologic characteristics impose? If any, are they of significance in the perverted condition following intestinal obstruction?

On the other hand, take a spherical gland like the thyroid, for example; how are its cells activated to like function in like time? What more convenient method than by the interwoven blood-stream with its hormones and varying coefficients of osmotic pressure? How different seems the arrangement of the intestinal mucosa!

§ J. W. Draper Maury has taken the name John William Draper

From these epithelial cells we know that the blood carries certain bodies which stimulate certain secretions.[1] This is a recently acquired habit and a highly specialized function, though older and less specialized than either sympathetic or central nerve control. Blood-stream messengers were doubtless used by our acardiac ancestors, for Draper[2] demonstrated nearly seventy years ago that hearts were a secondary contrivance and quite unnecessary to the maintenance of circulation. A more remote ancestral method of interglandular communication may have been the bathing of one pavement cell by the secretion of its next fellow. This method of stimulation in vertebrates is universally recognized in the activation of trypsinogen by enterokinase. Do not certain other substances follow the path of habit and of least resistance through the intestinal lumen? Surely, the experimental studies of Roger,[3] Matthews[4] and Pilcher[5] as well as our own, suggest this view. Furthermore, what other significance is to be attached to the terminal arrangement of the circulation in the small intestine? Free and lavish as is this blood-stream, its avowed architectural plan seems throughout the vertebrates merely for the purpose of hastening great volumes of blood to and from the intestine at the digestion period. Direct vascular interglandular communication appears minimized—definite lateral communication must have been provided had it been found functionally advantageous or necessary.

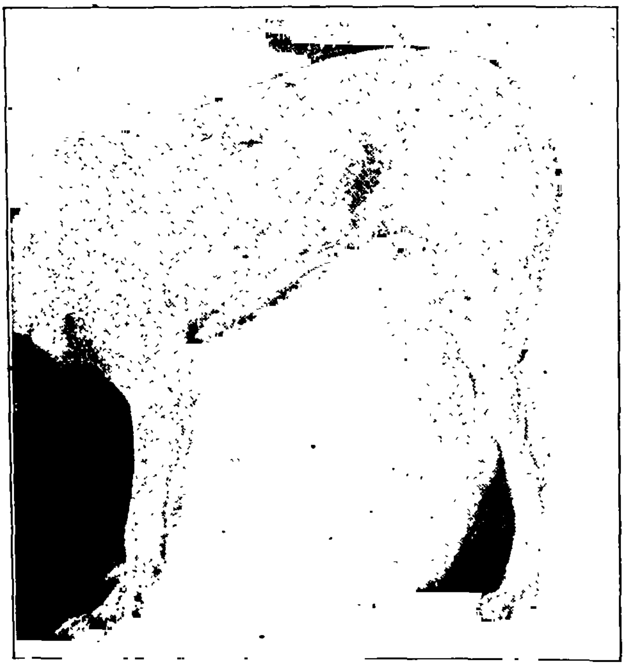

Fig. 1.—Animal in late hours of untreated duodenal obstruction. Posture is due to tonicity of hind leg muscles. Often walk on hind toes. Tendon reflex exaggerated.

Embryologically, as Schulz[6] says, the analogues of the digestive tracts of the higher forms are first met with in mollusca. This relationship must not, however, be thought of as too close, because, among other things, so important an element as pepsin, for example, has not yet been positively identified in the invertebrates. It is significant, however, and germane to a study of obstruction that the great mid-gut gland of mollusks, although it contains glycocoll and is commonly looked on as liver, partakes at least as much of the nature of the vertebrate pancreas as of liver. Necessarily, being the chief organ both of assimilation and of digestion, it also functionally resembles our own highly specialized intestine. Originally there existed a free channel of communication between the cells of this gut-hepato-pancreas—a sort of general cellular washway. In vertebrates, however, a wide anatomic separation of the gland units (the liver and pancreas) with resulting ducts, has restricted the primitive method of cell-bathing to the intestine alone.

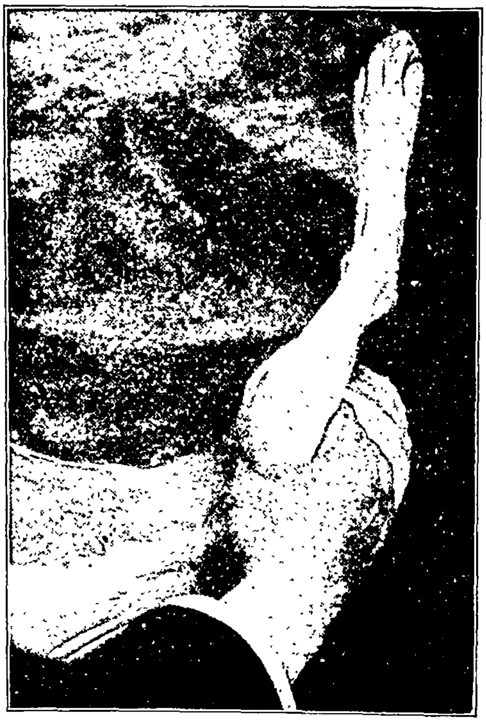

Fig. 2.—Relaxed hind leg of duodenally obstructed dog. Note that toes are together. Hand grasping thigh, gently.

These abstract considerations are valuable because of their vital importance in every-day work. If we would seek for the cause and relief of human ailments, recourse must be had for intelligent hypotheses, not in purposeless leaps in the dark, but in the friendliest possible adaption of both our phylogenetic and ontogenetic evolution to experimental thought.

The belief that death in duodenal obstruction is caused by the actual interruption of enteric exchange thus seemed logical. What had been put together through untold ages of striving by millions of ancestral species could not without quick fatality be rudely set apart. Walter Cannon, in a personal note, justly complains that certain of us have too long looked on the alimentary canal as a highly ingenious contrivance of rubber tubes to be spliced and lopped at will. In the same connection, Pavlov[7] says, "The digestive process is a synthetic construction, all parts of the organism working together." The human animal in altruism and in intelligence surpasses all others. Physically, however, even among the invertebrates, as Schaler[8] says, man has many superiors. His glandular functions, as shown by Starling,[9] are as subject to the first-formed primitive influences as are those of any other vertebrate. How close is the relationship between biology and executive medicine! Finney's[10] conclusions as to the fundamental importance to surgery of a biochemical rather than a purely mechanical interpretation of the problems of gastro-intestinal perversions, are certainly pointed and timely.

It was not then by fortuitous guess that we began to feed the mucosa of the jejunum and ileum of one dog into the stomach and short intestinal segment of a duodenally obstructed dog. A reestablishment of the hypothetic simple signals of our primitive ancestors by putting together what the obstruction had taken apart should theoretically restore physiologic equilibrium and thus delay death. In a measurable degree this proved true.

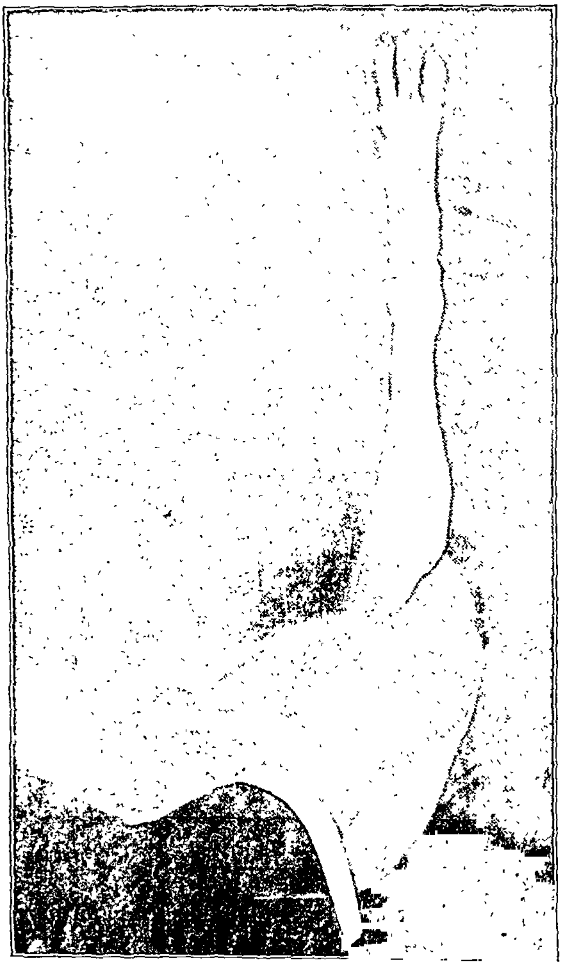

Fig. 3.—Spasm of leg shown in Figure 2, caused by pressure of fingers. This can be produced in normal dogs, but not so constantly. Toes separated.

Is there anything new under the sun? That the ancient Greeks attached a high sacrificial value to the entrails is humorously suggested by the following lines from Homer:[11]

> "They taste the entrails* and the altars load
> With smoking thighs."

This method of epithelial medication has in part answered the question suggested by earlier studies, "Does the intestine detoxicate by the addition of an anti-enzyme or does it save life by offering a larger field for absorption?" It is also germane to Bolognesi's[12] thoughtful studies on the chemistry of the blood in intestinal obstruction.

As in the case of delayed chloroform poisoning, the muscular twitchings spoken of by Howland[13] and Whipple[14] were good clinical evidence of the degree of obstructive toxemia.

The posture which was due to the tonic spasms of the hind extremity muscles was frequently characteristic. So also was the carriage of the hind leg in walking. It is not unlike the swing of paraplegia in man. If death be due to glandular inactivation, the various coefficients of the pulse should afford reliable measures of the intoxication, for Rogers,[15] quoting Loeb, thinks that the heart-beat itself may be due to enzyme action. Adult dogs seem to have as unstable thermo-dynamics as young humans.

TABLE 1.—SERIES A; DOGS FED MUCOSA *

NO. OF DOG	AVERAGE PULSE RATE	HRS. LIVED AFTER OBSTRUCTION	REMARKS
6	---	120	First dog fed Mucosa; only moderately sick.
8	---	127	Moderately sick.
20	148	103	Animal was a pup seemed resistant to toxemia, rapid emaciation.
40	146	174	Operated on at end of 168 hrs. for gastro-enterostomy. death in 6 hrs.
45	114	102	Operated on at end of 96 hrs. for gastro-enterostomy. death in 6 hrs.
49	160	120	Pulse rose from normal to 180 in 15 hrs. Animal very toxic.
63	144	127	Peculiar condition: abduction of outer toe clonic spasms, rapid emaciation.
72	123	163	Operated on at end of 6th day for gastro-enterostomy. died in 19 hrs.
75	140	180	Mucosa stopped at end of nine days Spontaneous intestinal fistula.
78	109	150	Very marked muscular tremors.
94	140	102	Condition very good throughout.
99	138	118	Condition good up to last 24 hrs. when marked tremors began.
112	128	57	Very marked tremors. condition good.
116	151	102	No tremors but marked rigidity of hind-quarters.
117	146	102	Condition good but animal extremely weak.
13	1787	-15 | 1847	

137=Av.P.—123=Av.length-of-Life-when-fed-Mucosa:

* In several animals a late gastro-enterostomy was made in hope of saving life. Futile because too much toxemic damage had already been done.

Hence, the rectal temperature has not appeared to be a reliable guide. It was usually but little changed by uncomplicated duodenal obstruction. Length of life, measured in hours after obstruction, obviously afforded the surest index of the efficacy of any form of treatment.

METHODS

Two series of fifteen dogs each have been prepared as follows: Under profound ether anesthesia in each case, the duodenum *has been sectioned and infolded just aboral to the major* pancreatic duct. All animals were treated exactly alike as regards dressings, postoperative care and free access to water. In Series A, however, each dog was given by mouth four times daily, about 30 c.c. of a watery suspension of mucous membrane scraped from the jejunum and ileum of healthy dogs which had been sacrificed by chloroform for the purpose. Approximately 400 c.c. of water were added to the entire scrapings and it was found that this suspension would keep on ice for about five days. No effort at standardization was made, but it was early observed that immediate treatment seemed more important than size of dose or later treatment.

One is tempted to speculate on the fate of numerous colon bacilli thus transplanted to unusual regions from the terminal ileum. Surgical introduction of such bacteria by implantation of a segment of the bacillus-bearing ileum into the duodenum had no visible clinical effect on two healthy dogs.

TABLE 2.—SERIES B; DOGS NOT FED MUCOSA *

NO. of DOG	AVERAGE PULSE RATE	HRS. LIVED AFTER OBSTRUCTION	REMARKS
1		60	Characteristic attitude of obstructed dog
2		72	
18	168	54	Characteristic attitude.
55	171	54	Tremors, high pulse, rigidity very marked.
57	175	126	Pulse high and rapid, animal very resistant to toxemia.
58	162	90	Marked rigidity and rapid pulse.
70	146	103	Marked tremors, spasticity violent reaction 14 hrs. after operation.
86	175	104	Very high irregular pulse, marked tremors.
87	161	78	High pulse condition excellent. walked up three stairs 12 hrs. before sudden death.
88		103	Marked tremors of whole body. Too vicious to take pulse.
89	194	54	Extremely high pulse but no rigidity or tremors.
90	194	30	Very high pulse but did not appear sick.
91	161	140	A young pup, very resistant to toxemia.
92	179	165	Marked tremors but condition otherwise good.
93	152	78	Very powerful dog shows relation between vital and physical strength.

12 2038-15 1311
170-Av.P. 87-hrs-Av.-length-of-life.

* The largest, strongest dogs were often the first to die. Physical strength no safeguard against obstructive autotoxemia.

In this connection the brilliant work of Moraschi, Ruiz and Natale[16] of Buenos Ayres should not be forgotten. They have shown conclusively, by injection into rabbits, that the intestinal contents from the obstructed segment became less toxic directly as the obstruction neared the rectum. While the obstructed duodenal contents were the most toxic, the feces of the sigmoid were definitely the least toxic of all. This intoxication these authors would attribute to a symbiotic action of the bacteria.

This is a totally new conception, for prevailing opinion until recently has been that these bacteria themselves were the source of the fatal toxemia. The impression that we have gained, however, is that the bacteria were facultative parasites and that at least the major part of detoxication was accomplished by the epithelial cells themselves. Orojejunal regions which bacterially are almost sterile have well defined power to limit the toxemia of obstruction.[17] It is not easy to see why this primitive autogenous function, on the existence of which the interpretation of our provisional results is based, should have been relinquished by the cells most directly concerned, to be turned over to parasitic cells of alien species. It presupposes a true obligate symbiosis which is confessedly rare in nature.

There is another point; if these bacteria played so very important a part in intestinal metabolism, the giving of large doses of calomel, which Baumann[18] proved to have the power of suspending bacterial action, should be followed by quite remarkable changes in the host. Ought not the healthy to fall sick and the obstructed to recover promptly? Still another point tending to refute the bacterial origin of the toxemia has

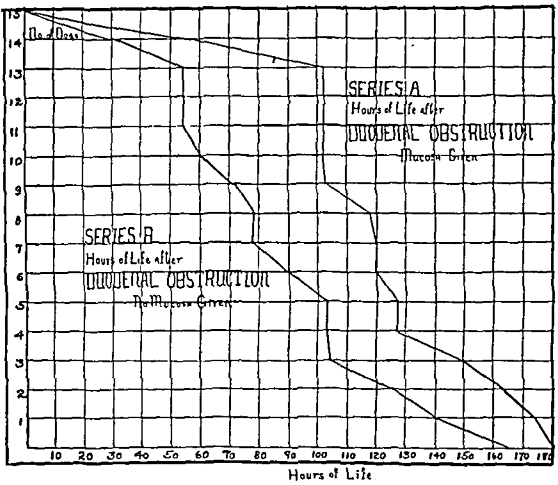

Fig. 4.—Graphic chart showing that the effect of epithelial medication is noticeable during the first 100 hours only of obstruction. *This fact and the parallelism of the subsequent charts strongly suggest a biologic reaction.* Average difference in length of life between treated and untreated animals was thirty-six hours.

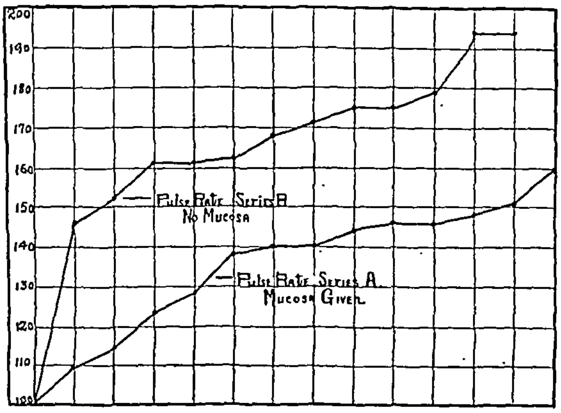

Fig. 5.—Graphic chart showing average pulse-rates in treated and untreated animals from operation until death. Note parallelism after initial separation of charts. Average lowering in pulse, 33 beats. Onset of high pulse usually within eighteen hours of operation. Too early for bacterial toxemia.

been made by Frank Wood, who says (personal communication): "We not infrequently see cases of fecal vomiting, in which, as soon as the obstruction is relieved, the patients recover promptly."

However this may be, those interested in the subject certainly owe a debt of gratitude to Roger and his pupils, who were the first to call our attention to the autogenous origin of obstructive toxemia. Whatever helpful parts the bacteria may or may not play, it is a healthful sign of progress that they have been relegated to minor positions in the consideration of death in duodenal obstruction. Emancipation is welcome from the hereditary text-book dogmas of "nervous influences," "shock," "stagnation of contents" and "passage of bacteria and bacterial products through the stretched intestine." These interesting symptoms should be set aside in favor of the underlying modern conception of glandular interaction, interference with which is probably the fundamental cause of obstructive death.

Jejunal and ileac mucosa, if capable of prolonging life and lowering the heart-beat in duodenally obstructed dogs, might reasonably be expected to modify any cellular tissue changes produced by the toxemia. One might expect such changes to be seen in the liver. So widely differing, however, is the morphology of the liver-cell under what appear to be normal conditions that we have as yet been unable to determine, with any degree of certainty, that duodenal obstruction caused any visible changes in the liver-cells. E. T. Bell[19] of the University of Minnesota has shown that the amount of fat present in a liver varied widely with the amount and quality of feeding.

How reliable an index of function, therefore, the presence or absence of morphologic changes in an organ might be after duodenal obstruction remains to be seen. Schlutz[20] has recently worked on a newly devised chemical method which Tollens[21] hopes may ultimately add to our knowledge of liver function. Dr. Schlutz suggested its possible usefulness in these studies, and I have the privilege of reporting his provisional findings.† The method deals with the quantitative determination of glycuronic acid. This substance combines with certain poisons, notably camphor, and this pairing or detoxicating is thought to take place entirely in the liver. By giving camphor hypodermatically, therefore, it seemed possible to find some true index of the functional condition of the liver before and after duodenal obstruction.

[21] Tollens: Ueber Glucoronsaure u. Aetherschwefelsauren im Menschlichen Harn., Ztschr. f. physiol. Chemie, 1910, lxvii.

† From the Laboratory of Physiology, University of Minnesota.

In the single study of Schlutz completed to date the tables showed, first, that the nitrogen metabolism during camphor administration was well within the normal, both before and after duodenal obstruction; second, that the glycuronic camphor pairing decreased from 41 to 27 before and after obstruction. This may indicate that the liver function had been impaired.

SUMMARY OF RESULTS

1. Epithelial cells of jejunum and ileum given by mouth to duodenally obstructed dogs prolonged life in a series of fifteen animals by about thirty-six hours over a similar series to which they were not given.
2. The average pulse-rate of the treated dogs was thirty-three beats lower than that of the untreated.
3. The belief that we were dealing with a cytologic product was strengthened by the trend of the charts. These showed that beneficial action occurred early, just as in the case of any successful treatment by antibodies.
4. The chemical determinations in one animal showed a normal nitrogen metabolism after duodenal obstruction and suggested a decreased functional power of the liver in terms of glycuronic camphor.
5. This series is far too small to justify any positive conclusions. Its value is simply that of a suggestive working basis.

THE USE OF CALCIUM CARBONATE IN SOLID MEDIA FOR THE DIFFERENTIATION OF SUGAR-FERMENTING BACTERIA

ESPECIALLY OF THE COLON-TYPHOID GROUP *

ARTHUR J. BENDICK, M.D.
NEW YORK

Media containing lactose with litmus as an indicator for acidity have been extensively used for growing the colon bacillus and differentiating it from closely allied organisms. This type of medium is well exemplified in Wurtz's lactose litmus-agar which consists of a 1 per cent. lactose-agar colored with litmus. These media have several defects, chiefly due to the rapid diffusion of the acid, causing a general reddening of the adjacent medium. This necessitates having plates with few colonies and examining and counting while the colonies are still small. Also gas formation often occurs, ruining the plate.

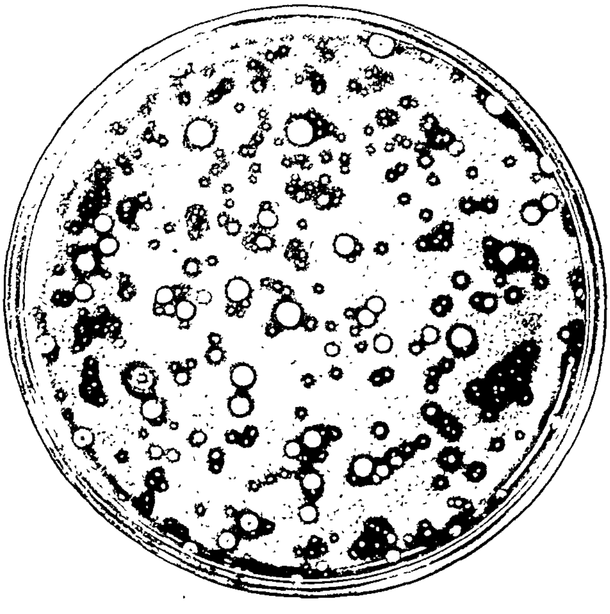

Fig. 1.—Culture of the colon bacillus, showing the clear area about each colony, where the chalk has been dissolved by the acid.

To overcome these disadvantages, media consisting of stiffer agar have been devised, on which surface smears are made. This is the type of the Conradi-Drigalski medium, which consists of a special nutrient 3 per cent. agar, to which crystal violet is added as an inhibitor for less resistant organisms than the typhoid bacillus.

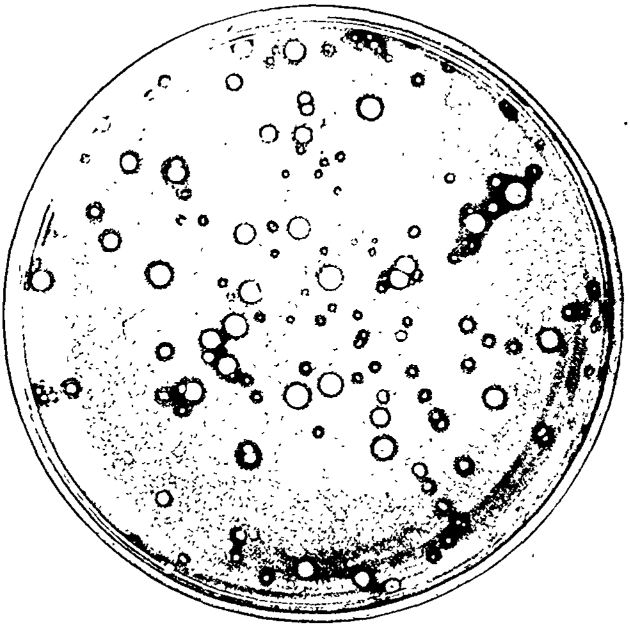

Fig. 2.—Mixed culture of the colon and typhoid bacilli. About each colon colony there is a clear, translucent zone, appearing as a black zone in photograph on account of plate being placed against a black background. This transparent zone is absent about the typhoid colonies.

With the intention of limiting the diffusion of the acid formed by the splitting of the lactose, I began to experiment by adding various alkalies to the medium. But such alkalies as NaOH and $NaCO_3$ when added in sufficient quantities had a deleterious effect on many of the organisms, and besides colored the medium an intense blue, which completely masked the production of alkalies, which production is of value in identifying typhoid colonies and those of the organisms of putrefaction.

A neutral agar was desired in which the acid produced by the fermentation of the sugar would be neutralized in order to prevent its diffusion. This result can best be obtained by using an insoluble alkali or alkaline salt.

The simplest and most efficient of the insoluble alkalies seems to be calcium carbonate — precipitated chalk. Being an impalpable powder, it is readily distributed throughout the medium, it exerts no inhibition on the organisms, is readily obtainable everywhere, and is inexpensive. Furthermore, the chalk in combining with the acid is dissolved; hence acid-forming colonies are surrounded by a clear zone. This clearing of the medium is a valuable aid in recognizing acid-forming colonies.

---

* From the Department of Bacteriology, College of Physicians and Surgeons, Columbia University.

The medium consists of:

	Gm. or c.c.
Agar	15
Liebig's extract	5
Salt	5
Peptone	10
Lactose	20
Calcium carbonate	4
Litmus solution	100
Water	1,000

The agar, Liebig's extract, salt, and peptone are dissolved in one liter of water either in the autoclave or over the free flame. This is then cleared with the whites of two eggs and filtered through cotton. No titration or adjustment of reaction is necessary. The medium should then be flasked, 250 c.c. to a flask preferably of 500 c.c. size. One gm. of powdered calcium carbonate is then added to each flask, and the whole sterilized in the autoclave. Finally to each flask is added 25 c.c. of Kahlbaum's aqueous litmus—according to Kubel and Thieman—(or an equal quantity of a solution of azolithmine); and 5 gm. of chemically pure lactose. Tube by pouring direct from flasks to tubes, keeping contents well mixed. Sterilize in an Arnold sterilizer for fifteen minutes on three consecutive days.

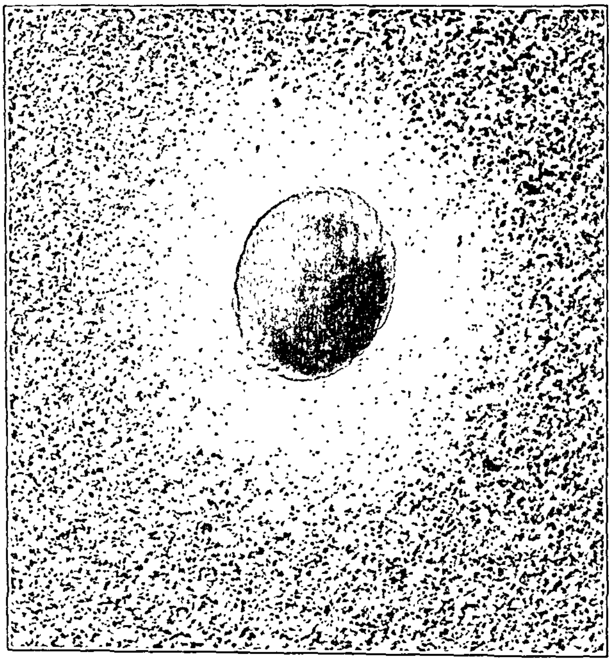

Fig. 3.—Deep colon colony, showing clear area.

In using this medium either surface smears may be made on plates or the tubes inoculated and poured. For most uses the poured plates give best results. To obtain a uniform distribution of the chalk throughout the medium, the tubes should be rolled rapidly to and fro between the palms of one's hands, and then by alternately depressing and raising the plugged end of the tube combining this with a rotary motion. This mixing should be done as soon as tubes are melted and while still hot. They are then cooled to 42 C. They may then be inoculated and poured.

Inoculated plates may be incubated fourteen to forty-eight hours at 37 C., or from two to five days at room temperature. Usually eighteen to twenty-four hours at 37 C. gives best results.

Acid production in this medium is shown by:

1. Dissolving of the chalk about the colony due to its combination with the organic acids.
2. Reddening of the colony due to the litmus.
3. Microscopically by the deposition of crystals of the calcium salts of the organic acids.

Differentiation between colon and typhoid colonies on this medium is readily made.

COLON COLONIES

1. *Surface.*—These are large disk-shaped colonies, slightly depressed in the media. There is a variable amount of clearing about them due to the solution of the chalk. The extent of clearing depends on the length of time the plates are incubated. Microscopically on focusing up and down, the chalk is seen to be dissolved just below the colony and about its periphery. Crystals of the calcium organic acid salts are usually seen.

2. *Deep.*—These are rounded or spindle-shaped, showing a very distinct clearing of the chalk for a considerable area about the colony.

TYPHOID COLONIES

1. *Surface.*—These are large white or bluish-tinged colonies showing no clearing of the chalk. Microscopically the amorphous granules of the chalk are seen to be both within and about the colony. No crystals of the organic salts are present.

2. *Deep.*—These are distinct colonies lying embedded in the chalk without solution of the chalk occurring.

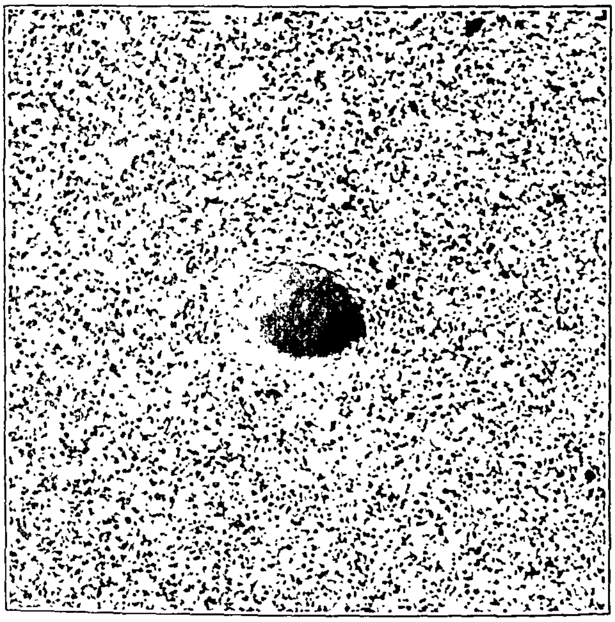

Fig. 4.—Deep typhoid colony.

For isolating the typhoid bacillus from feces, sewage, or contaminated water, 1 per cent. lactose and 1 per cent. saccharose may with advantage be substituted for the 2 per cent. lactose. Plates should be incubated fourteen to twenty hours at 37 C. Suspected typhoid colonies should be fished and inoculated into Hiss tube media or other suitable media for identification. I have on several tests isolated typhoid bacilli direct from the feces without enrichment.

The advantages of this medium are:

1. Neutralization of the acid as it is produced.

A. Crowded or well-diluted plates may be used with equal advantage.

B. The period of incubation is not limited.

C. Gas formation is greatly lessened, probably owing to the neutralization of the acid as soon as it is produced, thereby preventing it from being further broken down.

D. Acid formation is more clearly shown and its extent may be gauged.

2. Simplicity of the medium:

A. Stock meat extract agar may be used by simply adding chalk, lactose, and litmus.

B. The medium is neutral in reaction without titration or adjustment. The acidity of the meat extract is neutralized by the chalk, giving a neutral agar on which slight alkalinity or acidity is readily shown.

This type of medium may be used in growing and identifying any organism in which the fermentation of any sugar is the basis of its differentiation. For some organisms such as the pneumococcus and streptococcus, meat infusion agar may be substituted for the meat extract agar. Any of the sugars may be used instead of the lactose. The percentage of sugar may be varied from 1 to 5 per cent.

In conclusion I desire to acknowledge my indebtedness to Prof. P. H. Hiss for many valuable suggestions, and to Mr. Bosse for the accompanying photographs.

PINNING FRACTURES THROUGH A CANNULA WITH THE AID OF THE FLUOROSCOPIC SCREEN *

ROBERT T. MORRIS, M.D.
Professor of Surgery, New York Post-Graduate Medical School
NEW YORK

Last year I had occasion to remove a pin from a bronchus with a pair of alligator forceps inserted through the trachea. The fluoroscopic screen was employed for watching the movement of the forceps within the chest cavity. An account of this procedure was published in *Surgery, Gynecology and Obstetrics,* May, 1910.

It occurred to me at the time that if pins could be removed so easily with the aid of the fluoroscopic screen a reversal of the process might allow pins to be put in with facility in certain fractured bones which are not readily kept in place with splints.

At the present time I am engaged in experimental work along this line of observation, and publish a preliminary note on the subject quite as much for the purpose of pointing out difficulties in some cases, as in showing how this resource facilitates our work in other cases. We are now enabled to avoid open operation in certain cases in which open operation is otherwise indicated, and we can hold the ends of fractured bones in position in some annoying cases in which open operation would not be quite justifiable.

The work can be done in large part with such instruments as most surgeons have at hand, but it has seemed best to make up a case of instruments particularly adapted for the new work. A special table also was constructed with various slides, so that any part of the anesthetized patient could be conveniently exposed to the *x*-ray in front of the fluoroscopic screen. Dr. L. Kast made the first helpful suggestions in ways for using the fluoroscope for this work, and Dr. Howard T. Lewis, under the direction of Dr. F. H. Albee, has assisted in much of my work and in planning conveniences.

In fractures of the smaller bones the fluoroscopic part of an ordinary fluoroscope can be detached and used to better advantage than the large screen.

The instruments consist of trocars and cannulas, which are inserted obliquely to points of fractures; bone-drills for cutting channels for dowel-pins; tampers for pressing dowel-pins into place; an alligator forceps for removing badly placed dowel-pins; and segments of silver or German-silver wire of different diameters, to be cut up into requisite lengths with the file for dowel-pins.

When a dowel-pin is to be inserted the patient is anesthetized. Up to the present time I have depended on general anesthesia, but shall use local anesthesia in selected cases after a little more experience.

The steps in order are as follows:

1. A proper area of skin is sterilized.
2. The fluoroscopic screen is held in a convenient position for observing the site of fracture.
3. One or more assistants make traction and manipulate fragments until they are seen to be in position.

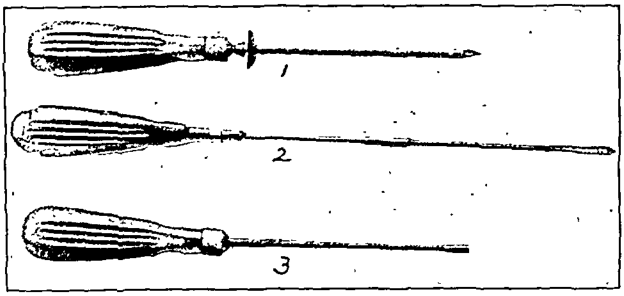

Fig. 1.—Three instruments of the special set (Kny-Scheerer Company, New York): (1) cannula and trocar with short point; (2) drill to fit snugly into the cannula and to project beyond its lumen; (3) tamper for pressing dowel-pins into place.

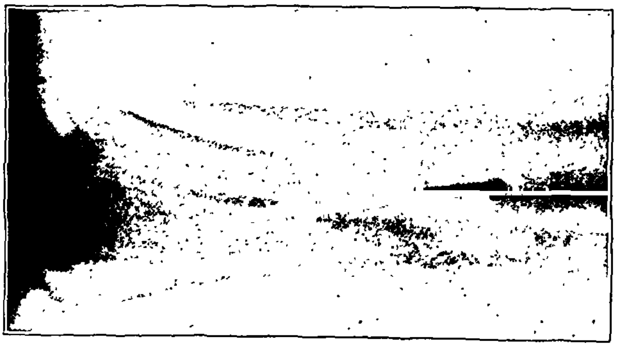

Fig. 2.—An accident to be avoided. Fragments were held accurately in position and pin appeared to be entered properly. This radiograph, taken next day, showed fragments out of position.

4. A trocar and cannula are inserted through the skin, and carried obliquely to a chosen point near the site of fracture.
5. The trocar is removed, leaving the cannula in position.
6. A drill is passed through the cannula, and transfixes both fragments which are to be pinned.
7. The drill is removed, and a dowel-pin of suitable length dropped into the cannula.
8. The pin is pressed into place in the drill holes with the aid of a tamper.
9. The cannula is removed, and a trifling dressing applied over the skin puncture.
10. Customary splints are applied to relieve stress on the dowel-pin.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Now that surgery is leaving the interior organs and getting back to bones again, this simplification of method for fastening fragments together promises to become a resource of considerable value, in well-selected cases. The entire procedure of introducing the trocar and the cannula, drilling fragments, and putting in the pin, is observed through the fluoroscopic screen as though one were watching his work through a window.

Dowel-pins are supposed to be left permanently in place, and I have so far had to remove only one which worked out of a fracture of the neck of the femur after union had been obtained. The number of pins to be used in any given case and the length of pins will depend entirely on the judgment of the operator. For a fractured rib or clavicle a single pin less than an inch in length should commonly suffice. In fractures of larger bones I have used pins two or three inches in length. When we are dealing with a short fragment, easily rotated, as in fracture of the inner condyle of the humerus, two pins are likely to be required for accuracy of adjustment.

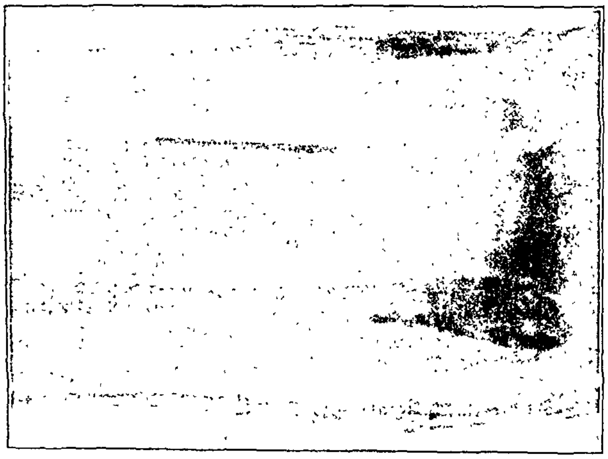

Fig. 3.—Same case as Figure 2; observation from another point of view showed pin not traversing fragments at all, but pushed alongside of tibia instead.

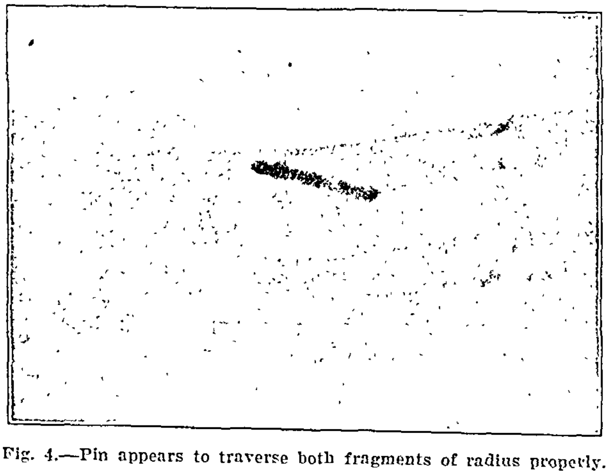

Fig. 4.—Pin appears to traverse both fragments of radius properly.

In cases in which fragments of smaller bones are not readily brought into position by assistants, an incision sufficient to allow the entering of a tenaculum or bullet forceps may be made (a refractory fragment is thus held in place), and the procedure is then completed with the aid of the fluoroscopic screen. This avoids the necessity for long incisions required for the introduction of Lane plates, and avoids extensive injury to soft tissues such as occurs in common methods of wiring fractured bones.

In one case of separation of the distal epiphysis of the humerus, and in another case of fracture of the radius with interposed tissue, it was necessary to abandon the work with the fluoroscopic screen and to make long open incisions, because neither traction nor manipulation, nor yet the use of fracture forceps, allowed the fragments to be brought into good position. I mention this point to show one of the limitations of the new method.

In a number of cases examined with reference to the idea of introducing dowel-pins, it was observed that ordinary splints sufficed to hold fragments in good position, and nothing further was attempted. It would have been meddlesome.

The chief accident likely to occur in the introduction of a dowel-pin is sliding the pin alongside of a bone instead of through the drill openings. This I have done twice, once in a spiroid fracture of the tibia (Figs. 2 and 3) and once in a fracture of the humerus. If one watches the fluoroscopic screen closely and has a clear picture, with the screen moved to two or three points of observation while he is at work, the accident is not likely to occur. It is best avoided by pressing the cannula against the bone with considerable force, and keeping it snugly in place between the moments of removing the drill, and of entering the pin.

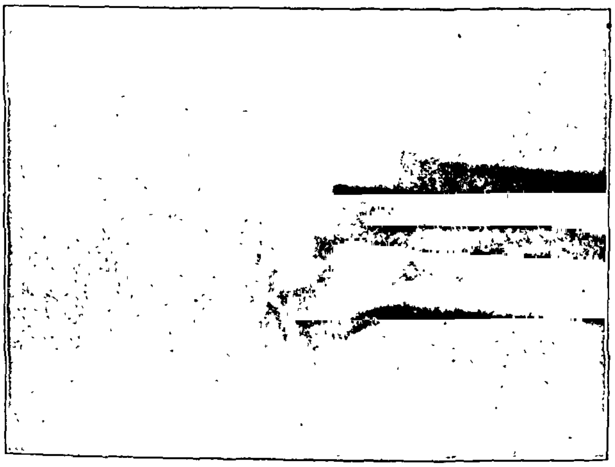

Fig. 5.—Same case as Figure 4; from another point of view. Pin traversing upper fragment of radius but missing lower fragment.

In Figures 4 and 5 the pin traversed the drill opening in one fragment properly, but missed the opening in the other fragment, even though I took away the screen, made a small incision, and then held the lower fragment in what appeared to be good position with a pair of bullet forceps.

One of these failures, illustrated in Figures 2 and 3, was due to observing the site of fracture from one point of observation only. In the other case (Figs. 4 and 5), with a small open incision, failure was due to my allowing the lower fragment to slip out of place at the moment when the pin was introduced, not using the screen for that point of procedure. No matter how well fragments seem to be kept in position with dowel-pins we must use the customary splints in addition, because during the period of osteoporosis pins might loosen under stress.

In old un-united fractures I have preferred up to the present time the long open incision and the use of Lane plates or wiring, for the reason that the ends of bones in such fractures usually need to be freshened. In selected cases of old un-united fractures I shall later experiment with dowel-pins, adding the resource of Bier (blood injection), but suitable cases for this experiment have not as yet been found in my clinic.

In cases in which we have interposed tissue, as for instance, in fractures of the patella, the dowel-pin will not be a proper resource, but it promises to have a field of usefulness in our every-day work.

The time for using the dowel-pin is ordinarily five or six days after the receipt of a fracture. At this time if we have used splints or extension apparatus, or both, exudates have undergone partial absorption, and the area is protected against infection by an established local hyperleukocytosis.

Just as this article is ready for the press, Dr. Kast suggests that accidents due to observing fracture sites from one point of view only, may be avoided by employing two *x*-ray tubes simultaneously, placing them at points which allow a view of fragments from two directions, without the necessity for changing the position of a fractured limb.

616 Madison Avenue.

EXPERIMENTAL AND CLINICAL WORK TO DETERMINE THE VALUE OF LANE'S BONE PLATING [*]

WILLARD BARTLETT, M.D., AND W. R. HEWITT, M.D.
ST. LOUIS

A visit to Mr. Lane's clinic at Guy's Hospital inspired an inquiry into the practical utility of the traction appliance, one of the most ingenious mechanical procedures which has ever been adapted to surgical therapeutics. In pursuit thereof, thirty-four screws, about half of them infected, were driven into the long pipe bones of dogs, and withdrawn at intervals, varying from one hour to seventy-one days, to determine the force needed to dislodge them, it being presumed that our surgical interest in most fractures does or should cease in ten weeks if all goes well.

In addition fifty-two patients were operated on, at periods ranging from a few hours to eight months after the injury. A critical study of the results is undertaken after a lapse of from five weeks to one year, respectively.

REPORT OF EXPERIMENTS

EXPERIMENT 1.—Immediate withdrawal, small dog, March 18, 1911. No. 3 ⅜-inch screws.

	Pounds
Left femur	75
Right femur	74
Right humerus	78
Left humerus	90
Average	79¼

This animal died under the anesthetic. hence simply a preliminary test of resistance to withdrawal was made. The bones averaged about 1 cm. in diameter and the cortex about 2 mm. in thickness. I am indebted to Dr. Erlanger for suggesting a self-registering spring-balance which was used in this and all succeeding experiments.

EXPERIMENT 2.—Two days. Infected April 29, 1911. One No. 3, ⅜-inch screw in each femur and humerus. Medium-sized yellow dog. Tumor on lower jaw. No attention paid to asepsis; wounds not sewed up. Died May 1.

Dr. Garrey helped withdraw the screws with direct forceps, etc. Stinking yellow pus in each wound; peritoneum dissected by it extensively.

	Pounds
Left humerus	44
Right humerus	10
Left femur	40
Right femur	42
Average	34

Pulled with double wedge forceps may make result too low and not wholly the consequence of infection. It would seem early for screws to loosen.

EXPERIMENT 3.—Ten days. March 18, 1911. Small, white mottled bitch. One, ⅜-inch, No. 3 screw in each femur and humerus. All wounds aseptic and sutured. Brand No. "1." Right ham.

March 31, 1911: Withdrawn after death, three days ago.

	Pounds
Right femur	42
Left femur	80
Right humerus	75
Left humerus	100*
Average	74¼

* Wire broke.

All wounds aseptic, healed.

EXPERIMENT 4.—Twenty-seven days. April 22, 1911. Small, 4-pound grey bitch. One slit in each ear; without any asepsis; wounds left open. Six No. 3 screws, ⅜-inch long were driven in both humeri and femurs; one right radius, also one left tibia. May 19, killed by chloroform.

Original	Control
42 right humerus	44 (infected)
6 left humerus	66 (infected)
42 right femur	66 (clean)
58 left femur	76 (clean)
37 average	63 average

Radius and tibia not drawn.

Right humerus, skin healed. Granulation tissue around screw-head. Cortex absorbed (in bottle).

Left radius, open granulating wound, cortex absorbed on near side. Screw perforated bone through cortex of opposite side. No lesion on far side (bottle).

Right radius, skin healed, pus and granulation tissue around screw-head. Some absorption of cortex (bottle).

All bones on front leg showed great thickening of bone about absorption locus.

Right femur, healed, normal appearance.

Left femur, bone appearance normal.

Left humerus, granulating wound open; cortex absorbed. Screw pulled at 6 pounds, caught in cortex of one side only. Control-bone broke at lesion without pulling screw, 66 pounds.

Thickness of cortex, 1.5 mm.

Average diameter of bones, 7 mm.

EXPERIMENT 5.—Forty-two days. April 11, 1911. Largest black dog, weight 66 pounds. No. 3 screws, ⅜-inch in each femur, humerus, ulna and tibia, 8 screws in all. Killed May 23, 1911.

Original		Control
75	R. humerus	90
120	L. humerus	180 (fail)
166	R. femur	
136	L. femur	Thickening to level of head
160	R. radius	
82	L. radius	115 granulations
150	R. tibia	142
	L. tibia	
127	average	131¾ average

---

[*] Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[*] Because of the space that would be required, the case reports are here omitted, but the complete article appears in the Transactions of the Section, and also in the authors' reprints, a copy of which will be sent by the authors or by THE JOURNAL on receipt of a stamped and addressed envelope.

[*] Experimental part from Surgical Department of Washington University. Clinical part from St. Louis City Hospital.

All wounds healed by first intention. Left tibia preserved to show screw-head embedded under tendon in fibroma, size of small marble. Around screw in left femur thickening to level of head. In left radius, evidently an infection. Granulations, absorption of cortex around screw and thickening of adjacent bone.

Experiment 6.—Sixty days. March 25, 1911. Brand III. Yellow bitch, weight 15 pounds. A screw in each femur and humerus, No. 3, ⅜-inch. Killed May 24, 1911.

Original	Control
57 R. femur	68 bone broken at normal hole
60 L. femur	69
96 R. humerus	63
110 L. humerus	48 granulations (Path)
80¾ average	62 average

All wounds healed clean, screws bright. Bones (three) look as if screws had just been inserted (except left humerus). In left humerus slight osteoporosis around screw, and cortex elevated in ring surrounding it (slight). Left humerus to pathologist.

Original at sixty days pulled higher than controls.

Experiment 7.—Seventy-one days. March 21, 1911. In each femur and humerus one screw, size No. 3, ⅜-inch. Smallest Lane drill. Brand "11," right ham. Killed May 31, 1911.

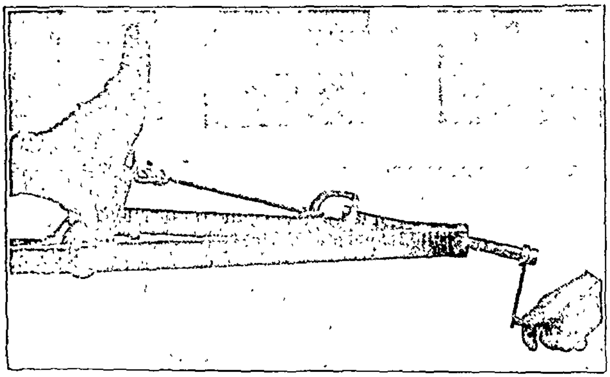

Fig. 1.—Traction appliance attached to table and in use.

Original	Control	Diameter mm.
100 R. femur	88	9
0 L. femur	112	11
130 R. humerus	128	9
125 L. humerus	110	
118 1/3 average	109½ average	

All skin wounds healed.

All except left femur looked as if screws had been freshly driven. Screws bright; contour of bone unaltered. Left femur infected, granulations, osteoporosis, thickening. Average thickness of cortex, 2 mm. Average diameter of bone, 10 mm.—1 cm. Screws are 1 cm. long. Dog smaller than average used.

An average pull of 95 4/5 pounds is required to dislodge clean No. 3, ⅜-inch screws, from dog bones with average cortex of 2 mm. after they have been in place from one day to seventy-one days. On the other hand 41 7/9 pounds will accomplish the same thing with infected screws. There was but one exception to this rule; here it required 110 pounds at sixty days to withdraw an infected screw, when the average of controls on this dog was but 62 pounds. In the dog the skin heals in a few weeks over the infected screw, but this has little effect in the tractive force required to dislodge it. An interesting phenomenon is the constant absorption of bone cortex around infected screws and a thickening around this area. Often the screw-head was almost hidden completely, so in one instance, apparently, Nature takes good care of an infected foreign body in dogs.

We are indebted to Drs. Opie and Smith for microscopic study of several bones in which screws had been driven and extracted. In Experiment 4, the left humerus presented an absorption locus around the screw and surrounding this crater there was an elevated ring. This latter proved to be young bone with osteoblasts to be seen in many fields. Osteoblasts were determined in the area where absorption was taking place and a diffuse infiltration of lymphocytes marked the tissue surrounding which was apparently the defect made by the screw.

The left humerus in Experiment 6 presented practically the same microscopic picture in every particular.

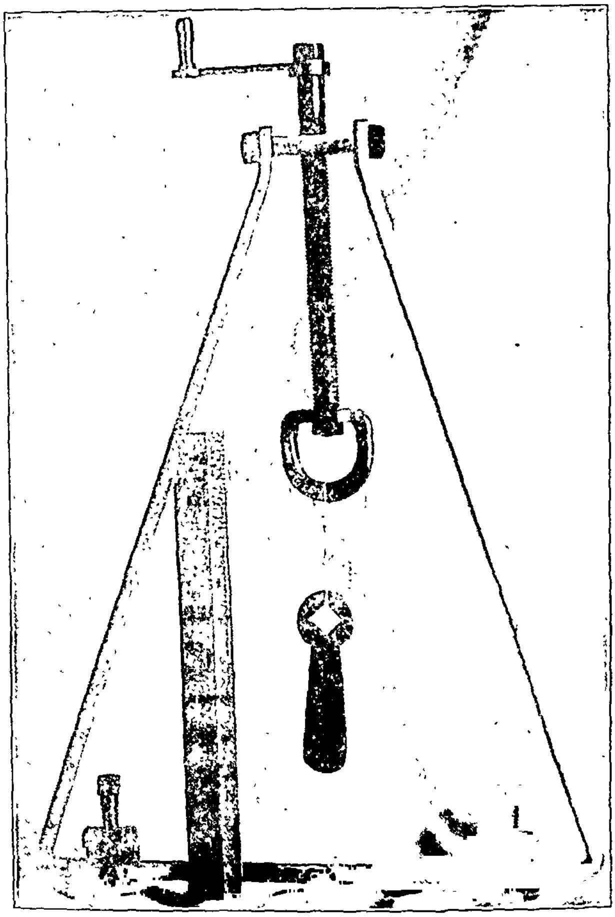

Fig. 2.—Traction appliance in detail.

A clean screw and the bone in which it is imbedded look just the same whether viewed when inserted or seventy-one days later. In other words, no macroscopic reaction occurs unless infection takes place.

It is of more than passing interest to note that clean screws, which have lain in bone for more than sixty days, required, in these experiments at least, more traction for their dislodgement than did their controls. If the same experience is had with the human subject, it is not devoid of interest so far as fractures are concerned in which union is delayed beyond the usual period.

As stated above, a pull of more than ninety-five pounds was required to withdraw the average clean screw of No. 3 gauge, from bones of about 2 mm. cortex. Now, the corresponding human bones have a much thicker cortex; moreover, we use No. 5 and No. 7 screws which are much larger in every dimension, to say nothing of the fact that as many as ten of them are imbedded at one time. It does not require much mental effort to picture the great amount of force needed to tear such a plate out of an aseptic wound at any time in its history, provided only it has been correctly applied; viz., by means of a drill the size of the screw barrel with the screw threaded to its head.

Of course, we take into consideration only a direct pull on the screws. As to leverage sufficient to break a plate or tear out a screw, that is quite another matter; it is for this that splints are used. Since not an infected screw dropped out in all my experimental work, it stands to reason that it is some external influence which loosens them in the human subject when infected. No doubt, this is the leverage exerted by the fragments which are not kept immobile long enough for healing to take place in the presence of a foreign body, as one experience with compound fractures has shown to be possible in certain instances.

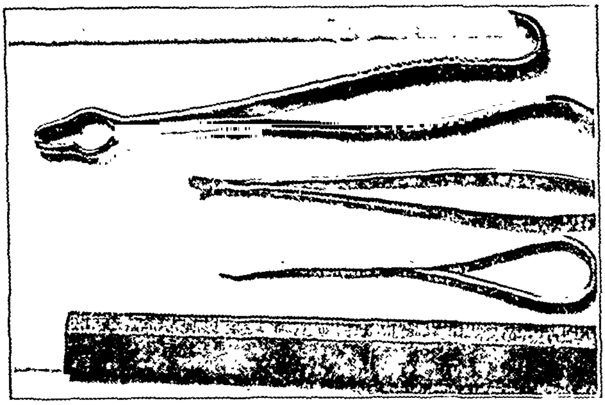

Fig. 3.—Bone forceps (Lane's), screw-holder (Lane's) and screw-driver.

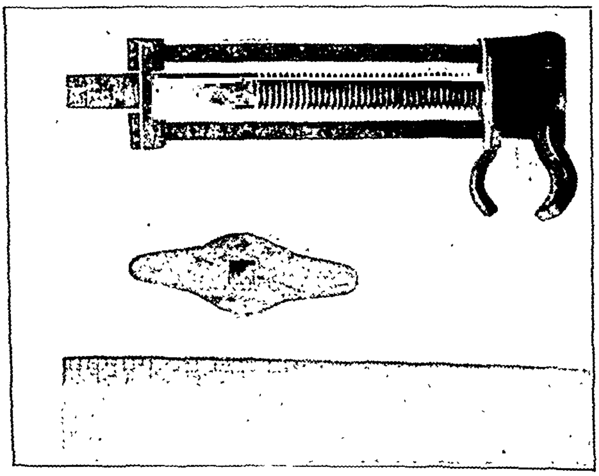

Fig. 4.—Embracing instrument.

CLINICAL DATA

At the end of this article* will be found the full histories of our fifty-two patients. We are unable to trace twenty-three from the time they left the hospital, and one is too recent to be of value; thus, we have for final study twenty-eight end-results.

Forty-three wounds healed by first intention, five were infected, one was left open to granulate, and in three instances, the history makes no mention of this feature. Only three of the above infections were in clean cases.

A solid union was obtained in twenty-five cases; non-union resulted once; two patients have died, and one operation was performed only five weeks ago.

Eight plates were removed; five of them being in simple fractures. One had compressed the musculospinal nerve; one occasioned a refracture (Case 11), one was infected at the time of operation, but as to indications for removal of the other two, we are not certain, since we did not take them out.

Five of these fractures were compound; two of them healed by first intention; two were infected; one granulated over the plate and went on to complete healing. Three of them got solid union, and in three the plate had to be removed.

There was a fatal result in two instances:

Patient 2, a chronic alcoholic, died of pneumonia, eight days after a fractured clavicle was plated. This case was badly chosen.

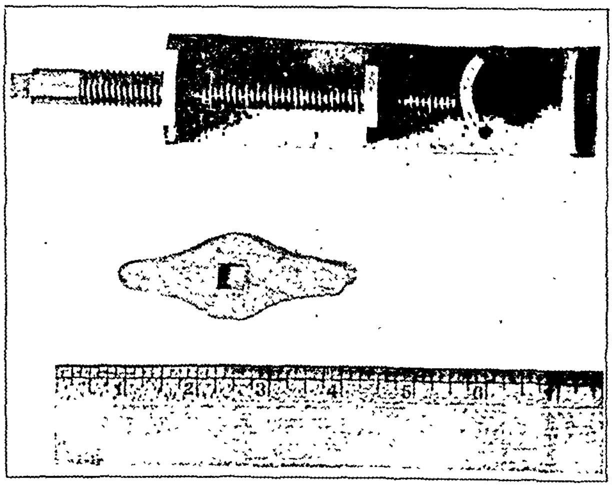

Fig. 5.—Embracing instrument.

Patient 5, another chronic alcoholic, managed to obtain whiskey from a friend a few days after the operation, became intoxicated, developed delirium tremens, saturated a thigh dressing with urine and feces, became infected and died on the fifteenth day.

This gives us a mortality of 3.84 per cent., which is not to be treated lightly where the operation is done for cosmetic or functional impairment alone.

We regret that we cannot give ultimate details in more cases. By letter, personal calls, etc., every effort to follow our patients was made, but many of them were "floaters," who had no permanent address.

If then, these statistics leave something to be desired, it must be remembered that most of these were cases picked as being too difficult for other forms of treatment, and that our city hospital patients are frequently poorly nourished and of the worst possible habits. In private practice one of us traced all his eight cases. Every patient got first intention, also solid bone union with perfect functional result. (W. B.)

Our city hospital is a training-school for doctors, hence the possibility of infection is greater. Doctors and nurses change, misunderstandings as to splints and dressings occur and hence a method gets an unusually severe test, to say the least.

---

* See footnote at beginning of the article.

A refracture which occurred in Case 11, after plating, is of singular interest. Seventeen days after his humerus had been plated, this patient took off his dressing, swung his arm free, and something snapped. On a second operation, the three screws in the upper fragment were as they had been left, while the remaining three held firmly a triangular fragment of bone which they had torn out of the lower half of the shaft. No 11 is really not a plating case at all. We failed to make a plate hold here; the case is included merely for its allied interest.

Cases 13, 14 and 16 are interesting from the fact that all three illustrate successful surgical treatment of greatly impaired musculospiral nerves. Surely this is an argument in favor of the method at times.

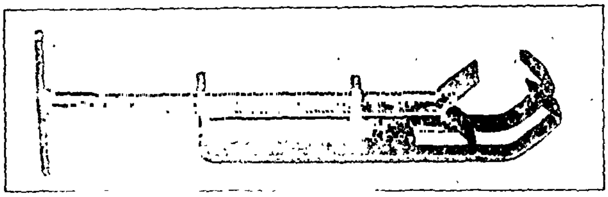

Fig. 6.—Embracing instrument.

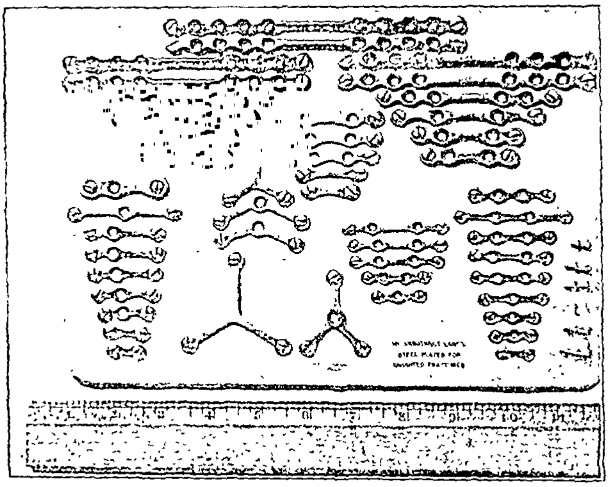

Fig. 7.—Lane's bone plates.

Case 24 will repay a perusal in its entirety. Here the ulnar nerve was sutured, the ulnar artery ligated, a number of tendons sutured, the ulna plated and other structures partially approximated in a compound injury; all these processes were accomplished with an ideal result.

A rather extensive operation was done on Patient 28. After plating an oblique fracture of the tibia, we did the same thing for a fibula which was broken in two places with a 2-inch fragment disposed at right angles to the axis. As a result, both wounds healed promptly and the man now does hard work on foot all day long.

Patient 36 was carrying trunks for a living—if his statement is to be believed—six weeks after we had plated a spiral fracture of the tibia, also a double one of the lower end of the fibula.

No amount of abstract reasoning can govern every case. Merely an effort is made here to show what our experience would indicate regarding a choice between forms of treatment.

Open	Closed
GENERAL ANESTHESIA	
Always used, fairly long.	Often used, short.
INFECTION	
Can almost certainly be prevented in clean case by modern technic.	Not to be reckoned with.
DISABILITY	
Much shortened, especially in lower extremity. Of great importance to wage-earners and the aged; *more so in summer.*	Much longer, especially if an oblique fracture and if extension is required.
NON-UNION	
Preventable as far as interposition on tissues is concerned.	Interposition of soft tissues apparently a common cause.
ANATOMIC	
Perfect if primary healing.	Rarely perfect, often deforming.
FUNCTIONAL	
Perfect, provided primary healing is secured.	Often better than anatomic would lead one to expect.

If we heard Mr. Lane aright, he told us in London, last summer, that he plates every case. It is our opinion, however, that the surgical world will never be quite so radical.

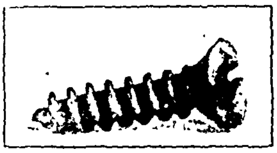

Fig. 8.—Lane's screw.

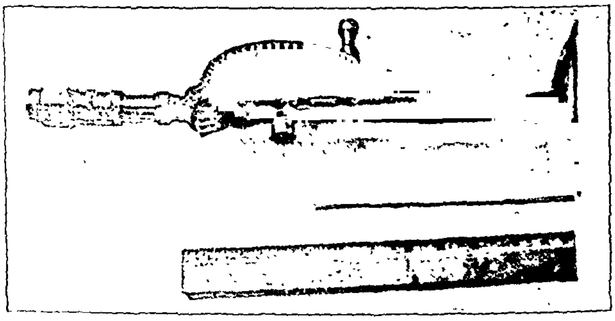

Fig. 9.—Drill-press and drill.

We try to get a result by the closed method in any fracture of any bone that can be placed and held in accurate position as shown by x-rays. Lane's treatment is never applicable to one who is a bad operative risk. No consideration of function can offset a risk to life.

Lane's plating is the best form of treatment known to us, for non-union or mal-union, and is indicated in all fractures which cannot be readily kept in place. It cannot, however, be recommended as a harmless procedure in the hands of surgeons generally. It is something of a specialty and requires its own extensive armamentarium; at the same time it will tax the mechanical resourcefulness of the best operator.

We advise waiting a few days before operating, or until the initial shock is past, bleeding has ceased, and a wall of granulation tissue partially protects from infection.

For a leg fracture not too near the ankle, traction to any degree required can be obtained and the force rather evenly distributed by applying it at the heel of the patient's shoe. A lace-shoe large enough to permit of free dorsal padding is used after a "screw-eye" has been driven through the mid-line just in front of the heel and anchored in a thin steel plate similar to an insole (Fig. 1). Our traction appliance is shown in Figure 2.

Make an incision that reaches the bone by the most direct route, which permits important vessels and nerves to be avoided. Where there is over-riding, the incision does not have to be as long as one would suppose, since traction lengthens it markedly. None but the most rigid asepsis can avail here. The skin is covered with towels, clamped to its cut edge. No fingers go into wounds and no instruments that have been touched are allowed to come in contact with exposed tissues. All needles and threads are handled with forceps, threads being mildly antiseptic.

Long-handled instruments permit of great leverage; they also enable an operator to work without danger of a hand getting into the wound. Figure 3 depicts Lane's bone forceps and screw holder, together with our own simple screw driver which any mechanic can make.

One need not concern oneself about periosteum; in fresh cases the work will be done within this envelope, but where the operation is undertaken for deformity or non-union at remote date, the periosteum is not likely to be opened. In any event, one should hug the bone and handle the soft parts as gently as possible.

It will often be found when the fragments are exposed that the *x*-ray is not an infallible guide. We occasionally met with a double fracture when the *x*-ray showed but one, and were frequently surprised in other ways.

In a recent fracture, over-traction is exerted until the ends of the fragments are separated by ¼ to ½ inch, after which one of the embracing instruments shown in Figures 4, 5 and 6, is applied. This lines up and guides them as the tension is relieved, with the effect that all spiculæ are forced to dovetail by muscular traction so perfectly that the break can hardly be seen. The "embracer" holds a Lane plate of the desired size which can now be screwed in at leisure.

This technic reduces the difficulties of the procedure to a degree which can be greatly appreciated by the operator, who has done this work with merely the armamentarium advertized as Lane's outfit, and especially appreciated by one who has attempted it with the instruments used in general bone work.

Another value of an embracing instrument is strikingly shown in two cases in which Dr. Carson, head of the department of surgery, recently operated. After applying the Martin instrument, he simply packed the wounds and allowed them to granulate. They healed within the usual time and both patients were discharged from the hospital with solid bony union. In a personal communication, Dr. Carson assures us that no harm was done to the bone by the long-continued pressure of the metal clamp.

We use Jessup tool steel and have many plates made to fit a given injury, after the *x*-ray picture has been seen. Mr. Lane's own set of patterns is shown in Figure 7. Plates of Jessup English steel can be molded during the operation to a bony inequality by heating in the flame, bending as desired, and then cooled gradually by dipping end-wise into boiling water, after which they are ready for air or fluid of any temperature.

Mr. Lane long ago called attention to the importance of using screws threaded to the head, as in Figure 8, and drills of the same diameter as the stem of the screw, the flanges being made thus to cut their own way into the cortex. These rather obvious mechanical principles have not been universally followed, and the results of such a neglect can be imagined.

The long drills used by us and the simple but effective mechanic's "press" used to drive them are shown in Figure 9. A screw may turn in its socket when a dull drill burns the bone; we have wrapped wire or silkworm around bone and plate in a few such cases with satisfactory results.

Wounds must be entirely dry before they are closed; this makes the use of a drain superfluous in clean cases, if, indeed, its use be not a menace to primary healing. Every tissue plane must be accurately reunited by layer sutures until the surface is reached.

The ideal skin closure is made with subcuticular suture of catgut, after which no change of dressing is recommended until the patient is discharged at the end of several weeks. Immobilization is required for as long a time as would be the case if no open operation had been done. We like to use plaster of Paris, though in many instances board or metal splints have been applied for a few days until swelling has subsided.

THIRTY YEARS' EXPERIENCE WITH FRACTURES AT MINNEQUA HOSPITAL: TREATMENT AND RESULTS[*]

R. W. CORWIN, M.D.
PUEBLO, COLO.

No attempt will be made to cover the field of fractures, but this paper will briefly state how we deal with fractures at the camps, plants, and hospital of the Colorado Fuel and Iron Company which employs from 15,000 to 17,000 men; including their families, about 80,000 individuals are to be cared for medically, a task made none the easier by their speaking forty-seven languages, and by the fact that not a few understand no English.

In the period above mentioned, 11,035 fractures have been treated by us. Many of our camps are located several hundred miles from the hospital.

A patient is prepared in the following manner for transportation:

SOFT PARTS

Contusion: Application of cold or wet dressings.

Slight lacerations: Dry sterile gauze dressings.

More extensive lacerations: Meddlesome cleansing avoided. Application of wet mercuric bichlorid, diluted alcohol, normal salt or 2 per cent. solution of iodin.

The covering of a wound with dry powder or closing it without free drainage is discouraged. Iodoform and other disagreeable dressings are strongly tabooed. The patient suffers enough from his injury without being made an object of disgust to fellow passengers en route. The well may tolerate or become indifferent to offensive odors, but the sick are distressed.

HARD PARTS

1. Wrap leg in plain cotton, bandaging very loosely with roller bandage, using simply enough to hold the cotton in place.
2. Elevate the leg for convenience of applying bandage. The leg should be extended and steadied by assistant making traction on foot. The leg should now be encased. Plaster-of-Paris bandage is the simplest method of applying plaster.

---

[*] Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

3. To avoid constriction, always cut the cast on each side; also always cut bandage holding cotton.

4. Reapply upper part of cast and tie same in place with bandage, which may be easily loosened. Never fail to instruct attendant to loosen bandage if the foot swells. This sort of splint may be applied to any part of the body needing special support.

On train: stretcher and mattress, but no springs.

On arrival at the hospital: General rules (as many as practicable): preliminary examination, bath, rest, little manipulation: *thorough examination*, under anesthetic; x-ray, two planes at least; temporary dressing until shock and swelling will permit of permanent dressing.

SPECIAL FRACTURES

Cranial: General Rules: Explore all scalp lacerations, no matter how trivial; explore all severe scalp contusions, by incision if necessary.

For opening the skull, the Hudson drill is preferred.

In fracture of cranium, remove as little and replace as much bone as possible. If a large piece must be removed, place it in normal saline solution, return it to its proper place and anchor by sutures.

To control hemorrhage in diploe, apply wax or lightly pack with long fiber cotton.

In every skull fracture, give hexamethylenamin (urotropin) freely; the first three or four days, 100 grs. each twenty-four hours.

Basal Fractures: Hexamethylenamin (urotropin).

Decompression as a routine has proved somewhat disappointing, except in progressive pressure-symptoms when it should never be neglected.

The mortality from this class of cases must necessarily be high, whatever the procedure.

Facial Fractures: Next to life, deformity should be considered. Observe symmetry. Many fractures have been compound.

Check hemorrhage. Mop out wound with tincture of iodin.

Replace bones, even spicules, if there be a possibility of establishing union. Hold them in place by suturing periosteum, or by drilling bone and anchoring with chromic catgut or kangaroo tendon.

Risk closing wound without drainage; it will often heal kindly, but on first intimation of abscess, reopen and drain.

In fractures of jaw, remember that teeth are a guide to apposition

Fine wire and dentist's clamp-bands will give greater satisfaction than external splints and bandage. They are cleaner, more easily observed and feeding is accomplished with ease.

SPINAL FRACTURES

Fractures of the spine at best are tragic. They usually mean a helpless and hopeless cripple, an object of pity, a constant sufferer, a living death, and a burden to self and friends. Often merciful would it be if paralysis from the seat of injury could extend upward as well as downward. Most of our spinal fractures occur at the mines, miles from the hospital.

Treatment: Immobilization at once, whether treated at home or transported. If the fracture be cervical, make gentle traction and support from the shoulder: if dorsal or lumbar, place patient on face between two tables. Make gentle traction and apply dressing, preferably plaster of Paris.

When to operate and when to treat otherwise, are vital questions needing prompt decision. Time may be an important factor. Theoretically, one's course is plain. When in doubt, explore. Practically, this is often unsatisfactory. Formerly our practice was to explore if in doubt. Now we hesitate. Our results are quite as satisfactory.

We never operate.
When death seems inevitable.
When the patient's consent has not been obtained.
When the case seems hopeless beyond reasonable doubt.
When the symptoms can be relieved by other means.

We hesitate to operate.
When there is profound shock.
When the case is of long standing.
When there is every reason to believe the cord is completely severed.

We operate when convinced that pressure on the cord may be relieved, whether it be from blood-clot, bone, or foreign body.

Early operations have proved more satisfactory than delayed operations.

Laminectomy under the most favorable conditions is frequently unsatisfactory, and under unfavorable environment may hasten death. Immobilization has given as good if not better results.

After treatment should be carefully considered in all operations on the spine. Incontinence of urine, involuntary stools, danger of pressure sore, lack of tendency of wound to heal, and danger of infection demand hospital and not home care.

We are resorting to expectant treatment more than formerly. We have more living proportionately to-day from nonoperative treatment than from operative treatment.

In most of our cases the injury is in the dorsolumbar region, and the fracture is usually through the body of the vertebræ.

STATISTICS ON SPINE FRACTURE

Total number of fractures of the spine (including all cases in which there were complications of internal injuries and instant death)	242
Number of cases inoperable, from complications or instant death	188
Number treated	54
Number treated by operation	18
Number treated without operation	36
Number living	25
Number operated and living (33 per cent.)	6
Number not operated and living (69 per cent.)	19

Pelvic Fractures: Dr. Moses Gunn used to say: "For fracture of the pelvis the doctor should do what is most difficult for a doctor to do: that is, do nothing." However, we find that immobilization by means of three or four 4-inch adhesive straps about the pelvis, or by plaster-of-Paris cast extending from the last dorsal to 6 or 8 inches down the thighs, for immobilizing the hip-joints, add materially to the comfort of the patient and shorten the time of repair. The usual fracture-boards should be omitted; the patient finds greatest ease in a "concave bed."

STATISTICS ON PELVIC FRACTURE

Total number in thirty years	334
Number operated on for injury of soft parts, such as rupture of bladder, urethra or rectum	36
Percentage recovering	94
Fatalities, total number	30
In cases operated on	5
In cases not operated on	25

FRACTURES OF LONG BONES

In fracture of long bones, setting accurately and retaining permanently without pressure must be our chief aim.

In simple fractures, for external support, we depend much on plaster of Paris, which in most cases, if properly applied after the disappearance of swelling, may be fitted to any position, cut so as to prevent pressure, admits of wide latitude of body movement, permits free examination of parts, is essential to cleanliness, is comfortable, inexpensive, and always at hand. When the plaster-of-Paris splint fails to accomplish all this, other splints are substituted or used in conjunction with plaster of Paris.

For internal support, when external splints have been shown to be failures by the x-ray, bone plating has proved very satisfactory—more so than wire, kangaroo tendon or staples. We avoid plating when tendon will serve, and are extremely cautious when there is little covering of soft parts: for instance, about the ankle. Rarely have we been obliged to remove plates on account of infection or irritation. When they have been removed, however, they have usually accomplished their purpose, and union has been sufficiently established so that external splints suffice. Frequent observation by the x-ray should be made that the condition of the plate may be known. Results of experiments with plates will be mentioned later.

Classification without detail is difficult, our records show the following results:

Number of fractures	11,035
(About 0.5 per cent. of the 2,000,000 cases of all kinds treated).	
Results have been classified under the following heads:	
Perfect results, per cent	66.87
(Those in which function has been restored and deformity is not objectionable).	
Imperfect results:	
Partial—Slightly deformed, per cent	8.75
Functionally or seriously deformed, per cent.	7.25
Wholly—Loss of function, per cent	3.33
Loss of limb (including fingers and toes) per cent.	9.11
Death, including all in which bone fracture is a prominent feature of injury, per cent	5.25

SOME DEDUCTIONS FROM EXPERIENCE

The first dressing of a compound wound is important; it cannot be done too carefully; it is often made worse by improper efforts. Better is it to let Nature cast off the foreign matter than to force it more deeply into the tissues by careless, meddlesome handling or too much scrubbing.

The closing of a compound wound without drainage is pernicious, and to add dry powder to a complete closure shows lack of experience. Suppuration is almost sure to follow a lacerated compound wound thus treated.

Provision for swelling is of the utmost importance; it cannot be emphasized too strongly; every physician knows that, but occasionally it is neglected.

The first examination cannot be too thorough. The condition of the patient, use of fluoroscope, *x*-ray, anesthetic and proper environment for future treatment, are of vital importance to both patient and physician.

We should neglect no opportunity to teach the laity the advantage over the home of a hospital, where there are nurses, resident physician and every convenience in case of emergency.

In head injuries the use of hexamethylenamin should be emphasized.

In spinal injuries act promptly but not hastily.

In fractures of long bones we should remember that

> "Functional results are more important than anatomic accuracy."
>
> Simple fractures, if possible, should always be treated by external support; but if reduction be difficult to obtain and maintain, unhesitatingly resort to the open method.
>
> The patient's general condition must always be considered.
>
> The medicolegal aspect must not be overlooked.
>
> Danger from infection, injury to a joint, vitality of bone, and environment for operation must be weighed.
>
> An incision should be sufficiently large to expose well the parts involved and make much manipulation unnecessary. Blind surgery involves risk.

The splint should be one that supports but causes no undue pressure, which may be removed at will for dressing or massage, and which permits the patient being taken out of doors for fresh-air treatment. Plaster of Paris will meet these requirements if properly applied and used, if need be, in conjunction with other mechanical devices.

The result of plating depends on method, material and position. Only he who is thoroughly prepared to do perfect aseptic surgery in a delicate and mechanical manner may expect uniform success in bone plating. Possibly electrolysis should be considered in connection with plate and screws of different material, or plate and screws each of two or more metals. Non-irritating material is imperative. A plate where there is little tissue over it, where the tissue is drawn over it, or where it fits poorly—or becomes loose—is apt to give trouble, and sooner or later must be removed. Better wait for swelling to subside before plating, if possible. Early plating is most apt to find firm bone.

Experiments with plates the past winter on lower animals indicated the following:

> Copper and brass plates or screws irritate and produce serious pathologic changes.
>
> Silver-plated plates, steel or iron plates and screws are non-irritating.
>
> A plate placed on the periosteum, or on the bone where the periosteum had been removed, produced the same favorable result.
>
> Arched or elevated plates resting as little as possible on the periosteum or bone are no better than flat plates resting throughout on the periosteum or bone.

Fortunately we are no longer obliged to resort to the Sir Astley Cooper method of reducing fractures and dislocations by bleeding, administering tartar emetic and placing patient in a tub of hot water until fainting results, in which condition, relaxed from exhaustion, the patient is treated.

Was is not Syme who said to Lister when a student, "We have reached the climax in surgery—you need look for nothing new"? That was only a generation ago. Another generation will do more for fractures than the past. Splints will no longer be needed, and plates, staples and wire will give way to a process of artificial welding, or better, artificial growing of new tissue.

Now, as a final word, I am aware of the little scientific worth of this report of thirty years' experience. It lacks detail, but detail would not improve it; but it does contain my effort of a generation, and I thank you for the privilege of presenting it; and if you will extend the privilege another generation, I will promise to give you a good report.

I wish to acknowledge the aid of my associates at the hospital, Drs. Adams, Senger, Dunlop, Schwer and Wilson, who have been of the greatest assistance to me in my work and in compiling statistics for this paper.

THE OPEN TREATMENT OF FRACTURES OF THE SHAFTS OF THE LONG BONES[*]

EDWARD MARTIN, M.D.
PHILADELPHIA

The limitation of the subject as indicated by the title is based on the hope that thereby there might be suggested a discussion more detailed than could have been provoked by a wider consideration.

The general indications for the open treatment of a fracture are afforded by the presence of a break accessible to intervention, which cannot be reduced and retained so efficiently that union without disfiguring deformity or crippling disability is reasonably assured. Further indications are afforded by the presence of a wound communicating with the seat of break and by non-union or vicious union.

The general indications governing the open treatment of fractures are:

1. Surgical cleanliness carried to its furthest development.
2. Operation as soon as it is clear that this is needful.
3. The securing of apposition with the least possible stripping of periosteum from bone or soft parts from periosteum.
4. The selection of an internal splint or support of the smallest bulk and of the easiest application compatible with the strength and persistence of the fixation desired.
5. Instruments and appliances which make the application of the fixation apparatus of choice easy and non-traumatizing.
6. The application of an external support which, during the period needful for union, prevents twisting and angling strains at the seat of fracture.

Surgical cleanliness necessarily implies that the fingers must not be put into the wound since patched rubber gloves often leak even before they are put on, and new ones, though they be of extra thickness, are generally torn or punctured at once if the rough bone ends are handled. Even in simple operations, as hernia and appendicitis, a large proportion of the rubber gloves used by the operator and his assistants are punctured. This can readily be demonstrated by blowing up the gloves after the operation and holding them under water.

---

[*] Read in the Section on Surgery of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911

Early operation is indicated because then complete reduction is most readily accomplished. Moreover, when one careful effort made under anesthesia fails to reduce, this end is rarely attained by subsequent efforts or by splints and bandages supplemented by extension: nor, if the principle of immediate operation when indicated be adopted is there need of a second anesthesia.

When *x*-rays are available, and this should be always, when operation is contemplated, they give such complete knowledge in regard to the position of the broken bone ends, that methods of examination other than inspection and measurement should be omitted, since the latter traumatize and give pain without compensating advantage.

The incision by which the fracture is reached should conform to the general principle that it is so planned as to injure no important structures, and is so placed and spaced as to make the seat of operation most accessible. Since it is rare that the convenient skin incision accommodates itself to the natural line of cleavage, the final skin suture, which should be most accurate, is sometimes difficult. The percutaneous and the lock stitch will be found serviceable.

The seat of the fracture having been exposed, apposition is secured by longitudinal pull, lateral traction, torsion and angulation.

Lateral traction may be applied by means of a metal hook passed over the broken cortex into the medullary cavity, or by tape carried around the shaft of the bone by means of a blunt curved needle.

By angling out over the arm of an assistant, the broken ends can be placed in apposition; straightening the bone then overcomes the resistance of the soft parts.

In many fractures which have not been operated on within a week of the time of injury, and particularly in old fractures, these measures of reduction often fail to overcome shortening. Unless this be so great as obviously to require resection, it can best be reduced by longitudinal traction applied directly to the upper end of the lower fragment. The simplest device for the attainment of this end is a stout canvas band, the middle of which is placed over the proximal end of the distal fragment. The two ends are then brought parallel with the limb, and into the loops with which each is provided is passed a rope, to which in turn are fastened weights.

In the case of fractured femur 100 pounds are required, sometimes double this; and we have been compelled to use nearly as great force in fractures of the forearm bones. The weights are allowed to exert their pulling effects for from five to ten minutes, traction being continued until there is an actual lengthening of about one-quarter of an inch. This over-stretching is distinctly serviceable in lessening the strain to which the buried fixation apparatus will be subject. Moreover, it allows an easy apposition of the broken bone ends after the weight is removed.

Apposition having been secured, and in the least traumatizing way, at times by simple incision and slight moulding of the parts, if there be no tendency toward reproduction of the deformity and if it seem probable that the good position secured by operation can be maintained by external splints, without internal bracing or support, the wound may be closed without placing in it any foreign body. If it seem clear that a bone suture supplemented by external splinting will be adequate, kangaroo tendon may be used. If the fracture be oblique and not likely to be subject to severe strain, screws, nails, staples or even tendon suture through drill holes will prove adequate. If by none of these means can the reduced fracture be retained in position, the steel plate is indicated.

If the fracture be of the femur and transverse not only is the steel plate indicated, but one of considerable strength, particularly in fat, muscular subjects, since by no means of splinting can we put the break completely at rest or protect it entirely from twisting or angling strains.

Since the tolerance of tissues to foreign bodies is inversely proportionate to the bulk of the latter, it is of vital importance, if plates be used, that these be of the smallest size compatible with the strain to which they are to be subject.

An experimental trial of the plates sold by instrument makers has demonstrated that these break at greatly differing stress, and that in some instances the force required to break them is comparatively slight. The break usually occurs at the screw hole nearest the seat of fracture, the point of greatest strain, and, as the plates are made, the point of the greatest weakness of the plate.

Because of such an accident having happened in our clinical work, we have endeavored to secure a stronger material than that usually supplied, and have had constructed of vanadium steel, by Lentz, a plate much stronger than that now supplied and so planned that it is reinforced at the usual point of breaking. It is probable that these large strong plates will have no application in regions other than that of the thigh, but since the femur is the most difficult bone in the body to protect from cross-strain after plating, there is distinct need when operating on this bone of an implement on which entire dependence can be placed. The major advantage of the vanadium steel is incident to the fact that great strength may be secured in small bulk, and that under ordinary clinical conditions it would seem almost impossible to break buried plate made of this material.

If plating be the operation of choice, it is absolutely essential that the drill for boring the screw holes be of such size that the screws may be driven in easily and yet may cut their own threads; as manufactured, they so vary in pitch and diameter that a tap is not serviceable. Many screws should be provided so that if one drives hard it may be readily replaced by another. The screws should be threaded to their heads and be of such length that they will reach the medullary cavity and not pass far into it.

In testing plates we have found that two screws on each end of a plate, driven through one thickness of the cortex will hold beyond the breaking strain of the plate, therefore, through-and-through screws and more than four are unnecessary.

On general principles the nearer the screws to the seat of fracture, the stronger the fixation; if, however, the screws be placed nearer to the line of break than one-quarter of an inch they are likely to tear loose if subject to a severe angling strain.

The fixation of the plate is greatly facilitated by instruments which will hold it in place while holes are being drilled and screws driven home. The most universally serviceable instrument is the Lohman clamp. These smaller clamps are often useful. The Lambotte forceps, or rather Lentz' modification of it, is useful, not only as a plate holder, but as a means of accomplishing that complete reduction which is sometimes prevented by spicules of bone.

The screw-drivers used should be those which hold the screw in jaws while it is being driven home.

When a strong plate is firmly fixed by screws the surgeon may feel that he can almost, if not quite, dispense with external support. Indeed the union seems as firm as would be, for instance, that accomplished in the same manner with dried bone. This is not the case. By twisting and rocking motions of the limb peripheral to the break, the line of fracture can always be made to perceptibly widen and close. In other words, there is always potentially slight motion at the seat of plating, or fixation by any other mechanical means. Unless this slight motion is reduced to its possible minimum by external splinting, loosening of the screws or other support is inevitable. This we have demonstrated by many experiments, having conceived the idea that it might be possible to apply an internal splint of such strength and firmness that without any external support it would hold the bone in place till healing had been accomplished. Moreover, there are many *x*-ray pictures which prove the same fact.

The after-fixation of fractures treated by the internal splint is best secured by a plaster-of-Paris casing, so applied that not only the joints on either side of the fracture are fixed, but that the muscles which act on the bone ends are also for a time kept at rest. This implies in fractures of the leg bone an envelopment carried up to the middle of the thigh. In fracture of the femur a cast from the foot to the ribs. In the forearm bones a cast from the midphalangeal joint to the shoulder. In the arm bone a casing including the shoulder and extending to the midmetacarpal region. These casings should be split while soft so that in part they can be removed, allowing the seat of operation to be inspected and massage and passive motion to be applied as soon as advisable.

As to the results of the open treatment of fracture. many are good, some indifferent and a few distinctly bad.

It is noteworthy that union is usually delayed, that the time of treatment is not materially shortened, that the results are not uniformly good. But, taken as a whole, they are infinitely better than could possibly have been secured by other than operative means.

Even in the cases clean at the time of operation, there have been a few instances of infection; this infection has, however, in two of my cases of femoral fracture, been of a peculiar type, becoming manifest in about three or four weeks after the time of operation and characterized in the meantime by a very slight elevation of temperature well below 100. The infecting organism was the *albus* and had no communication with the plate or seat of fracture, involving the subcutaneous tissues alone. In one instance, for example, the indolent abscess. formed some weeks after operation, was not even near the site of incision.

There has seemed to be a relation between the size of the internal splint and the promptness of final union. In other words, we have felt that the less foreign matter we put in the wound the quicker it got well.

As to the fate of the plates: We have taken them out unnecessarily, finding them clean and as firmly fixed as though they had been driven into wood. We have taken them out because of continued suppuration. We have left them in now for years nor have they excited any untoward symptoms. A woman recently presented herself, who was plated five years ago. She made a fairly prompt and complete recovery. For the last three months she suffered from pain in her leg. She had a varicose ulcer beneath the outer malleolus and a softened area over her plate in the lower third of the tibia. This had been perfectly quiescent in the intervening time. When proper support was given to her dilated veins the pain disappeared, as did the softened area over the plate, and she became completely able-bodied. What proportion of these buried plates, if any, give subsequent trouble remains yet to be proved.

Given the proper tools and appliances and intervention shortly after the injury, the operation is usually not a difficult one. Having performed it, we regard the subsequent external splinting as equally important in the securing of an ultimate satisfactory functional and cosmetic result.

ABSTRACT OF DISCUSSION

ON PAPERS IN THE SYMPOSIUM ON FRACTURES BY DRS. CORWIN, MORRIS, MARTIN, AND BARTLETT AND HEWITT

Dr. Herman E. Pearse, Kansas City, Mo.: I like to operate early. I have been told that it is better to operate late. I find a bone is the crystallization of lines of force, and that the crystallization ceases when the force is not applied, and begins again when it is applied; and so, if two pieces of bone overlap badly, I find rarefaction of bone, and the screw holds better if these cases are plated early.

As to cleanliness, we do not boil long enough; we do not get the skin clean enough; it is useless to paint it with iodin and begin to operate. It is criminal. It seems to me that every one who intends to do this work should at least read and follow the preparatory technic of Mr. Lane, which has been worked out by fifteen years of constant application. Nothing short of that is safe.

I have examined the stock of splints at different surgical instrument houses. They are all useless. They are all less than the minimum weight shown by Dr. Martin to be proper. They are capable of being bent readily between the thumb and finger and they break easily and will not hold. I commend particularly the remarks of Dr. Martin as to the weight, strength, size and material of splints.

I would again urge your attention to the remarks of Dr. Martin in which he speaks of the external application of splints. This external application should be made, but not by any means for so long a time as suggested. In the conduct of the fracture wards of our general hospital of some 300 beds (in an active city like Kansas City, many people are hurt). I have had occasion repeatedly to see most disastrous results from neglecting this. The proper internal splinting of the bone, with the closing of the external wound, gives such a degree of security that the limb is used with entirely too much freedom, unless motion is thoroughly restricted.

I should like to request those very active minds who are so constantly improving the size and the shape and the material of Mr. Lane's splint, and who are in so many ways improving the technic by shortening it, that before any further attempts are made to improve this operation, they prove out the technic as already established. For reproach is being brought on this operation by death from suppuration and by splints that are literally vomited forth when carelessly placed with poor technic. It is worth while to study the technic of the master who has placed this matter where it is, before attempting to improve it on reading his literature.

Dr. Fred B. Lund, Boston: We have treated fractures entirely by external apparatus, and the reason is that until the worth of Lane's plates was proved we had no other method of treating them. I know that for several years, with external apparatus alone, we have been getting a great many bad results; and I, too, was impressed last summer, as Dr. Bartlett was, with seeing the application of Lane's plates. I have tried them and I have succeeded and I have failed; but I sincerely believe that this is the first efficient means of internal splinting that we have had at our command, and that it will prevent a good many malunions and a great many non-unions and much suffering; and if proper attention is paid to the technic and a proper instrumentarium provided, as Dr. Martin and Dr. Bartlett have so wisely insisted, it is going to do a great deal of good.

But nobody should attempt these operations without a study of the methods of the master, Mr. Lane, and providing himself with as complete and perfect a set of instruments as he can get. I think that Dr. Bartlett's traction apparatus is going to be a great help and will greatly lessen the labors of the operator. It substitutes a perfect and powerful mechanism for the imperfect and comparatively weak aid of an assistant.

I have treated thirteen patients since last October, as follows:

(1) An old ununited oblique fracture of the femur in bad position; united in perfect position after plating. (2) A very bad, old, oblique fracture of the upper end of the femur without union four months after the injury; good results from plating four months after operation. (3) A bad transverse fracture of the femur plated, with failure, partly through bad technic and partly through lack of efficient external support. (4) Malposition accompanied by great pain in a transverse fracture of the humerus ten days before in a woman of 60, in which case external apparatus was unsuccessful; perfect result from plating. (5) Ununited fracture of both bones of the forearm four months after injury, with interposition of the muscle between the fragments of the ulna; plating, with very good anatomic and perfect functional result; ulnar plate had to be removed at the end of three weeks. (6) Malposition in fracture of both bones of the forearm, plated; both plates had to be removed at the end of ten days; the result was good. (7) Spiral fracture of the tibia with very poor position; perfect anatomic and functional results from plating. (8) Angular deformity fracture of both bones of the leg, three months after injury. Excellent results from plating.

The prolonged suffering which men get with non-union and malunion makes it worth while to operate on these cases and to use efficient operative means to secure good results. If one takes the trouble to learn how to plate these cases and to do the operation skilfully, the results are more than satisfactory.

Dr. W. Le Moyne Wills, Los Angeles: The greatest advantage of this method is that by the proper application of apparatus you can maintain from the first, perfect apposition of fragments. I operated on a patient by the Lambotte method two years ago. This case was one of epiphyseal fracture of the head of the left humerus. Seven days after the patient was hurt in the mountains, I operated on him. The effect is really not cosmetic; but he does not wear a low-necked dress. He now works in a brass foundry. He has a perfect functional result and I have the plates to prove it.

I have never claimed that this is an ideal method. It is not applicable to all cases. Nobody should do this operation who has not seen Lambotte do it or one equally skilled in use of his apparatus. I would be willing to have it used in case of fracture of my own femur.

When I reported nine cases two years ago at the San Jose meeting of the California State Medical Society, and admitted 25 per cent. of infection, I was severely criticized for that. I operated in this case since I reported those other cases. A man often does not admit that pus is present in his own work, but always sees pus and bad results in other people's work. It is a case of the beam and the mote. I have tried to be honest and report failures. But there is a perfect functional result in the case presented.

Dr. William Fuller, Chicago: It is my belief that practically every fracture, regardless of its location, type or kind, that is difficult to reduce or difficult to hold reduced, should be treated by the open method. On the other hand, fractures without obstacles to reduction, and calling for simple devices or means to retain the fractured ends of the bones in apposition, should be managed by non-operative measures.

I desire, especially, to endorse some of the points brought out in the papers by Drs. Martin and Bartlett. As to the somewhat complicated apparatus which is described and used by Dr. Bartlett for exerting traction on the extremities, it undoubtedly has a place in this work, but I am inclined to the opinion that it would be the exception. Personally, I prefer two strong assistants, besides the one directly concerned in the operation, who can generally make sufficient traction and counter-traction, evert or invert the limb, or employ other desired manipulations at a moment's notice. This leaves the operator and his first assistant free, and removes the necessity of touching anything but the instruments and the field of operation.

The dangers resulting from the open method of treating fractures are, in reality, slight. It has not been shown, to my knowledge, that tissues surrounding broken bones are more susceptible to infection than tissues elsewhere. If the organs within the abdomen were subjected to the same rough handling observed sometimes in operating on fractures; the stomach drawn out with vicious-looking hooks, the gall-bladder ablated without regard for adjacent structures, abdominal surgery would not stand where it does to-day. Tissues covering a fractured bone will heal just as kindly and promptly as abdominal tissues, if treated in the same careful, surgical manner. It is true that at present suppuration more often follows bone operations than other operations, but the reason is plain.

Just a word with reference to the postoperative treatment of fractures: Besides complete hemostasis, and accurate wound closure, nothing is so important in promoting satisfactory progress of the wound as extreme elevation of the extremity. It has a decided beneficial effect in preventing, as well as subduing, infection. The limb does not swell, all edema immediately disappears, the circulation is perfect, and pain is much less severe. This elevation is not accomplished by pillows, but by placing the limb on a well-padded splint, which should be suspended by pulley or otherwise at a right angle to the bed.

Dr. John Rogers, New York: The general impression which we carry away from this discussion is that "bone plating" is the best thing there is. I have had considerable experience with fractures in Bellevue. We have probably the largest collection of fractures there in the city. We have about fifteen or twenty surgeons there—all competent. Directly after this fixation method was first exploited, I think every fracture in the hospital was plated. As a result (I speak for myself as well as the others) we spent considerable time in taking these plates out. But there was one man in the institution who carried through his work with apparent perfect success, and I think he had only one failure out of fifty cases. On studying this result, to see why it was very much better than the results of the rest of us, I found that he had a complete set of these instruments, and kept his fingers entirely out of the wound. The rest of us were using the ordinary hospital appliances which were at hand and they were defective in the bone holder and one or two of the other instruments; and every one of those cases, in which the fracture was handled manually, suppurated, so far as I know. So not enough stress has been laid on the technic of doing these operations. Unless you have every appliance as originally introduced for holding these bones in place, do not try the operation. A little improvement on that bone-holder can be made by constructing it in the form of an obstetric forceps; so that the spread does not have to be so wide when the blades are put in the wound; but all the appliances must be employed or there will be trouble.

Dr. Frank Warner, Columbus, O.: I wish simply to emphasize the importance of position in the treatment of these fractures to prevent strain on the fragments. The surgeon should remember that if it be a fracture at the upper end of the femur, the tendency of the upper fragment is to draw forward and outward; consequently in the treatment of that fracture if plates have been applied or the fragments wired, the thigh should be dressed in flexion so as to avoid strain on the plates or wires. A fracture in this or in any other location, should be handled constantly with the cardinal thought in mind of preventing tension on the plates or wires by dressing the limb in such a position as will mean the least muscular tension on the fragments, for there is a constant tendency for any undue strain to break the wires or loosen the screws. As for example, take a fracture of the femur above the knee-joint; the tendency there, is of course for the gastrocnemius to draw the lower fragment back; so that in this locality the fracture should be treated with the leg flexed. The fractured member should be dressed in the same position as if there were no plate or mechanical appliance used to hold the displaced fragments in apposition. By adhering to this rule, less tension is put on the plates or wires by removing the muscular strain on the fragments. The splints should be constructed with proper windows so that the dressings may be changed without strain being put on the fragments. Or, if it be not practical to use a window, then in changing the dressings the greatest care should be exercised that as little strain be put on the fragments at that time as possible. Otherwise the wires will snap or the screws will become dislodged. A point equally important is that the surgeon himself or some one properly qualified should take care of the patients after operation. It is easy to have this operation made a failure if the surgeon looks after the patients only casually and occasionally, and substantially turns them over to an intern, an extern or a nurse to make the dressings. The success of the result will be in proportion to the subsequent personal attention given the fracture.

Dr. Rexwald Brown, Santa Barbara, Cal.: The kinds of apparatus now in use sometimes have discouraging features. Wires break and Lane's plates and staples frequently pull out or break because of leverage following their application. Lambotte and Parkhill apparatus invite infection, for along the screws are open pathways directly from skin to bone. Buried material only deserves attention: how much foreign material can be buried is open to investigation. The good reports following use of metal half-cylinders—a not inconsiderable foreign body—led me to devise a clamp which seems to have advantages over others used. [Dr. Brown then exhibited his clamp and explained the method of its application, all of which will be described in a paper to be published elsewhere.]

Dr. R. W. Corwin, Pueblo, Colo.: I should suggest that the plates be made thinner and smaller than some that have been devised. All who have seen Mr. Lane's work must appreciate the care he employs, and too much emphasis cannot be laid on this point. Iodin is of value in some cases, notwithstanding our Kansas City friend's views.

THE CLINICAL THERMOMETER AS A POSSIBLE DISSEMINATOR OF SOME COMMUNICABLE DISEASES *

EDWARD B. BEASLEY, M.D., D.P.H.
BALTIMORE

Until the discovery of the rôle played by insects in the transmission of disease, an air of mystery hovered over the means by which certain diseases were communicated. Probably no disease illustrates this point better than malaria. About twenty years ago, malaria was attributed to the miasmatic emanations which came, during the night, from marshes and swamps. When the anopheles mosquito was discovered to be the host of the malarial parasite, the puzzling atmosphere which had hitherto enveloped malaria vanished, and the etiology of one of our mysteriously transmitted diseases was placed on a scientific basis. We now know that the habits of the anopheles mosquito—so far as biting is concerned—are nocturnal and that marshes, swamps, etc., are its breeding-places.

At one time the fomites theory was regarded as practically the only way in which communicable diseases could be spread. This theory afforded such a simple and easy explanation of the subject that it became deeply rooted in the minds of both the medical profession and the laity. The discovery of bacillus-carriers and the recognition of mild cases (formerly unrecognized) of certain communicable diseases have contributed toward the displacement of the fomites theory, and sanitarians are relegating this theory to a rather minor position in the dissemination of communicable diseases.

The clinical thermometer, however, is an object which must be reckoned with when dealing with the spread of communicable diseases. The etchings on the clinical thermometer form ample harbors for countless bacteria. Very careful washing and drying, after use, will remove most of these organisms, but some will remain and they might as easily be of the pathogenic type as of the harmless variety. If an accurate clinical thermometer could be manufactured with an inner scale instead of the etchings, this source of danger would be partly avoided, but the construction of an accurate thermometer of such a type is, at the present time, mechanically impracticable.

It is a matter of serious regret that most thermometers receive a scant washing and drying after use. The presence of the mercury precludes the use of hot water and consequently a most careful washing becomes imperative, especially where no disinfectant is used. Only too often the thermometer is merely dipped in a glass of water and wiped; or else it is held momentarily under some running water and then dried.

It has long been contended that physicians, from time to time, spread communicable diseases. That their clothing on rare occasions has been responsible cannot be denied, but a more likely agent is the clinical thermometer which is used from person to person without the proper amount of care being taken in regard to its cleaning.

To test the bacteria-carrying power of clinical thermometers, a series of experiments was undertaken. Some thermometers were made, by a very well-known firm, to resemble clinical thermometers in every respect except that they contained no mercury. The mercury was left out so that these dummy thermometers could be easily sterilized by heat during the experiments.

Pure (twenty-four-hour) cultures of *Bacillus prodigiosus* and *B. pyocyaneus*—grown in Dunham's solution—were used to infect the thermometers. The general scheme of the experiments was to rinse the mouth for half a minute with the culture of *B. prodigiosus* and a sterile thermometer was then placed under the tongue. At the end of one minute the thermometer was removed and treated in one of the ways described later. Only one thermometer was infected after each rinsing with a culture. The method of procedure with the culture of *B. pyocyaneus* was identical with that of *B. prodigiosus*. These two organisms were selected as they are easily identified in mixed cultures and it is perfectly obvious that the thermometers must be infected, after use, with many varieties of bacteria found in the mouth. An additional reason for working with *B. pyocyaneus* was its pathogenicity, as it is this type of organism that we are most anxious to learn as much as possible about.

After treatment, the thermometers were dropped in sterile tubes containing Dunham's solution. This medium discourages heavy growths of most organisms and it has an inhibitory effect on oral bacteria as it is practically sugar-free. Those thermometers infected with *B. prodigiosus* were allowed to remain in Dunham's solution for twenty-four hours, at the end of which time a sterile platinum loop was inserted and several loopfuls were transferred to some sterile potatoes. Those thermometers infected with *B. pyocyaneus* were allowed to remain in the solution for four days, or until the green fluorescence of this organism appeared.

---

* From the Department of Preventive Medicine and Hygiene, Harvard Medical School.

B. pyocyaneus is occasionally found in the mouth and there are also, at times, three organisms (*B. buccalis fortuitus; Bacillus b* of Vaginal and *Micrococcus doseus*) present in the mouth whose growth on potatoes might be confused with *B. prodigiosus*. In addition, tap-water, once in a while, contains some one of these organisms and consequently it was thought advisable to carry controls through with the infected thermometers. Great care was taken to see that the thermometers were kept free from outside contamination and during their exposure they were handled with sterile thumb-forceps. The controls throughout the entire series were negative.

The particular methods used in caring for the thermometers and the results are tabulated below: (+= growth; —= no growth.)

SERIES I

After infection, the thermometers were rinsed in a glass of water for half a minute.

B. prodigiosus			*B. pyocyaneus*		
Trial 1	24 hours	result +	Trial 1	24 hours	result +
Trial 2	24 hours	result +	Trial 2	24 hours	result +
Trial 3	24 hours	result +	Trial 3	24 hours	result +
Trial 4	24 hours	result +	Trial 4	48 hours	result +

SERIES II

After infection, the thermometers were held under running water for one minute.

B. prodigiosus			*B. pyocyaneus*		
Trial 1	24 hours	result +	Trial 1	48 hours	result +
Trial 2	24 hours	result +	Trial 2	48 hours	result +
Trial 3	24 hours	result +	Trial 3	72 hours	result +
Trial 4	48 hours	result +	Trial 4	72 hours	result +

SERIES III

After infection, the thermometers were rinsed in a glass of water for half a minute and then carefully dried with sterile gauze.

B. prodigiosus			*B. pyocyaneus*		
Trial 1	24 hours	result +	Trial 1	96 hours	result +
Trial 2	24 hours	result +	Trial 2	96 hours	result +
Trial 3	24 hours	result +	Trial 3	72 hours	result +
Trial 4	24 hours	result +	Trial 4	96 hours	result +

SERIES IV

After infection, the thermometers were held under running water for half a minute and then dried with sterile gauze.

B. prodigiosus			*B. pyocyaneus*		
Trial 1	24 hours	result +	Trial 1	96 hours	result +
Trial 2	24 hours	result +	Trial 2	96 hours	result +
Trial 3	24 hours	result +	Trial 3	96 hours	result +
Trial 4	24 hours	result +	Trial 4	96 hours	result +

At this point *B. pyocyaneus* was abandoned for further experimental work with the thermometer as its fluorescence appeared both slowly and faintly.

SERIES V

After infection, the thermometers were kept under running water for three minutes and then wiped dry with sterile gauze.

B. prodigiosus		
Trial 1	24 hours	result +
Trial 2	24 hours	result +
Trial 3	24 hours	result +
Trial 4	24 hours	result +

SERIES VI

After infection, the thermometers were rinsed in running water for half a minute, then dried with sterile gauze. They were then allowed to remain in sterile thermometer cases for half an hour before being placed in Dunham's solution.

B. prodigiosus		
Trial 1	24 hours	result +
Trial 2	96 hours	result —
Trial 3	24 hours	result +
Trial 4	24 hours	result +

SERIES VII

After infection, the thermometers were treated similarly to those in Series 6, except they remained in the sterile thermometer cases for one hour.

B. prodigiosus		
Trial 1	24 hours	result +
Trial 2	24 hours	result +
Trial 3	96 hours	result —
Trial 4	24 hours	result +

SERIES VIII

Identical treatment as Series 6, except the time in the sterile thermometer cases was increased to two hours.

B. prodigiosus		
Trial 1	24 hours	result +
Trial 2	24 hours	result +
Trial 3	48 hours	result +
Trial 4	24 hours	result +

SERIES IX

After infection, the thermometers were put under running water for half a minute, wiped dry with sterile gauze and then placed in sterile thermometer cases for three hours before finally being transferred to Dunham's solution.

B. prodigiosus		
Trial 1	96 hours	result —
Trial 2	24 hours	result +
Trial 3	24 hours	result +
Trial 4	24 hours	result +

In looking over these experiments, it will readily be seen that the dummy thermometers had superior advantages (in being freed from the infecting bacteria) over the thermometers in actual practice. In most communicable diseases the saliva of the patients is thickened and in some diseases it is very tenacious. This condition would naturally give the bacteria a much better opportunity to adhere to the thermometer than where the saliva is thin and normal. The experimental thermometers were held under the tongue for only one minute, whereas, ordinarily in practice, they are allowed to remain from three to five minutes to insure good registration. In addition, the experimental thermometers were always washed immediately on being removed from the mouth, which fact did not allow the saliva to dry and become fixed. On the other hand, it would appear that conditions in actual practice seldom occur similar to those in Series 1. However, where two or more members of one family are ill at the same time, a careless physician might simply rinse his thermometer for a few moments and then use it on the second patient. Series 9 shows that a thermometer can retain live bacteria—capable of being recovered—after the thermometer is fairly well washed, dried and then placed in a case for three hours. Physicians in active practice must use their thermometers at more frequent intervals than this.

There are many diseases which might possibly be transmitted by clinical thermometers. Scarlet fever, diptheria, mumps, measles, typhus fever, cerebrospinal meningitis (epidemic form), acute anterior poliomyelitis, small-pox, whooping-cough, typhoid fever, tonsillitis, coryza, pneumonia, cholera, plague (pneumonic type), grip and some forms of tuberculosis may be mentioned as some of the diseases which might conceivably be disseminated in this manner.

In conclusion, it would seem necessary that physicians should keep their thermometers immersed in a true disinfectant if they would eliminate this source of danger to their patients. Formaldehyd solution would be a most satisfactory substance to use as, in contra-distinction to phenol (carbolic acid), it does no damage to the etchings of the thermometer. Until the city and state health departments give some attention to this subject, everybody who can afford to do so, should provide himself with a reliable clinical thermometer in order to avoid the use of an outside one which might prove to be the origin of some communicable disease.

EMPIRICISM AND PHARMACOLOGY IN THE MANAGEMENT OF POSTOPERATIVE CASES *

S. T. POPE, M.D.
WATSONVILLE, CAL.

> I never saw a purple cow—
> I never hope to see one;
> But I can tell you anyhow
> I'd rather see than be one.—*Gelett Burgess.*

I've never been a "postoperative case"—and I'd rather see than be one. I am sorry for any one who must be a "case" of any sort, but most sorry for those who in their postoperative experience have had insult added to injury.

It is not long ago that we tied together the thighs of our patients in perineal cases; enforced a strict dorsal decubitus on our celiotomy patients; denied them water for days at a time; forbade them food; refused to abate their sufferings with anodynes for fear of intestinal stasis; purged them unmercifully on the second or third day, and perhaps shot them full of nuclein. Patients have often said to me: "Doctor, I did not mind the operation, but really if I had to be scrubbed as I was, and must go without water for three days as I did, I would rather die than submit again to such an experience."

And while we are somewhat less strenuous to-day, still there is plenty of room for improvement in our after-treatment. These errors in judgment, on our part, are due to excessive solicitude.

In the first place, we starved our patients prior to their operation, fearing to have food in the bowels. The way some people hate their intestinal canals is a shame. One would think, to hear the average doctor talk, that the source of all earthly danger originates in this tube. We starved them so successfully before and after operations that many patients, when subjected to the toxic influence of an anesthetic, developed a fatal acidosis.

Acting on the assumption that postanesthetic vomiting called for an interdiction of food, we heightened the degree of this acid intoxication by further starvation. Or if we did give food, it was of such a nature that it was poorly calculated to combat the development of acid intoxication. We gave beef-tea or malted milk when we should have used carbohydrates, such as baked potatoes, cornstarch pudding or mush. I have often seen postoperative vomiting which had resisted all palliative measures cease immediately after the giving of these substantial starches.

Conti, in the year 1895, first demonstrated the presence of acetone in the urine after general anesthesia, but it has taken fifteen years for this danger-signal to arouse some of the medical profession. Ladd and Osgood[1] reported that, in 173 ether anesthesias by cone, 88.5 per cent. of the patients later showed acetonuria, while of 222 anesthesias by the drop method, 26 per cent. became acetonuric.

The administration of alkaline substances as an antidote is markedly beneficial in this condition, yet this measure is seldom employed or, if used, in such insufficient quantities that no advantage is gained.

We must recognize that the factors at work in the production of the acetone complex are active and large, and oft-repeated doses of basic salts must be absorbed. If sodium bicarbonate be employed, it will require several ounces a day, given by mouth, colon, or hypodermically, to neutralize the acidemia.

After all general anesthesias, it is a good procedure to let the patient drink repeatedly, at intervals, a glass of water containing a dram of sodium bicarbonate. If this is vomited, it serves as a good gastric lavage; if retained, it tends to forestall acid intoxication.

For colon absorption, sodium bicarbonate can be added to the normal saline in a 2 per cent. solution.

For intravenous or subcutaneous injections, 1 per cent. sodium bicarbonate or sodium citrate solutions have been used, but neither is to be recommended except in extreme emergency, because of its hemolytic action on the blood. Food and proctoclysis will usually do all that is necessary to combat acidosis.

Closely associated with the subject of starvation is that of catharsis. It must have been because intestinal stasis is a prominent feature of peritonitis and postoperative ileus that in the past, and partially in the present, we have feared fecal retention. As a consequence, we have brought our most potent charms to work on this innocuous symptom.

The existence of constipation is no more harmful in a postoperative condition than in normal health, and in the normal state its effects are purely mechanical.

It is true that some gas distention or fecal impaction may add to the discomfort of the patient, of course I do not here refer to massive impactions (which in themselves constitute a pathologic lesion); but constipation itself has never been proved a source of intoxication. The experiments of Alonzo Taylor[2] absolutely demolish the contentions of those timorous physicians who so urgently plead for purgation. Taylor has shown that in the absence of a definite infection, no toxic absorption results from intestinal stasis. Where there is an infected bowel, there is always diarrhea.

Auto-intoxication is a state of mind, and the effects of cathartics are largely psychic. Indican is not a criterion of intestinal intoxication. Experiments on dogs, in which the intestine is ligated to simulate constipation and an invasion of bacteria into the portal circulation, with subsequent bacilluria result, are not to be taken as homologous to simple retention of feces.

Strasburger has shown that the bacterial content of the bowel is about 60 per cent. of the dried residue; and that in constipation this is reduced, while in diarrhea or after purgation the percentage of bacteria is increased. For this reason William Mayo refrains from giving any cathartics immediately before operations on the colon.

Not only is the routine administration of cathartics unnecessary, but it is frequently harmful. After the ingestion of calomel it is always possible to detect occult blood in the stools. It is simply another toxic element in the system, and does not inhibit the growth of intestinal bacteria.

---

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[2] Taylor in Osler's Mod. Med., i, 273, 274, 276.

Magnesium sulphate is a decided cardiac depressant. It also has the capacity for abstracting needed water from the tissues, something that is exactly contrary to the demands of the occasion.

In fact, it should be our effort to keep the body well saturated with water before an operation. It is also true that the flat bowel of purgation, one whose muscular tone has been depressed by some cathartic, is that which later suffers most from distention.

And probably another demonstration of the paretic effect of chronic purgation is shown by the surgical cases recently reported by Lane, Finney and Mayo—those of colonic atony, redundancy, supposed fecal stasis, and auto-intoxication. Finney is unable to account for this atony; the habitual use of cathartics should be considered.

The bowels should be in a normal state for the average operation. This is best achieved by a restricted diet, low proteids and devoid of uncooked food. Vegetables that have not undergone the sterilizing process of cooking are a distinct source of danger at this time.

An enema on the morning of the operation is all that is necessary to relieve the colon of its contents and establish the most favorable intestinal condition. And on the resumption of feeding, the bowels will often move spontaneously about the fourth day, or if gas distention causes discomfort, or fecal masses in the sigmoid or rectum distress the patient, an enema will relieve the condition quite as thoroughly as a purgative, and will do no damage.

Certainly in postoperative vomiting or ileus or peritonitis, cathartics only add to the intestinal insult. It seems a hard lesson for us to understand, that in the absence of a definite endo-intestinal infection, it is not what is on the inside of the bowel that is doing the damage, but what is on the outside.

And in the use of enemata it is high time that we abandon the colon tube. Soper and many others have confirmed our suspicions; it is a miracle and a definite act of Providence when a colon tube ever enters the colon. It simply coils up in the rectum or sigmoid—in fact, it should be called a rectal dilator.

Fortunately for us, a high enema is not dependent on the necessity of being injected high. Any fluid placed in the rectum will be propelled into the colon by the normal reverse peristalsis. A short rectal tube is just as efficient as a long colon tube is supposed to be.

Where pain exists to a distressing degree after operations, we certainly have little justification for withholding morphin. By lessening pain we lessen shock and the possibility of postoperative ileus.

Yandell Henderson proposes the theory that excessive respiratory excursions produce an exhaustion of bodily carbon dioxid on which the respiratory center depends for stimulation. In the absence of carbon dioxid this center ceases activity, respiration stops, and a pathologic condition results, which he terms "acapnia," the circulation continues until oxygen failure ensues, vasomotor balance is destroyed and a vital crisis exists—this is shock.

Pain, by inducing rapid and full respirations, precipitates this condition—one actually gasps oneself to death.

It is also true that severe pain in any part of the body may produce meteorism. Bloating with gas may be just as marked from gall-stone colic as from strangulated hernia.

Morphin does not favor the production of ileus. It does constipate, but the production of one single cardinal symptom surely does not establish the disease. Used with judgment, morphin is a beneficent agent after operations. It masks nothing from the discerning eye; it fools only the foolish.

And when ileus does follow operations, the question first must be decided, is this mechanical or is it functional? Many patients are treated palliatively who should have their abdomens reopened.

If ileus really exists, its treatment is as varied as its nature is problematic. Certainly cathartics are to be excluded—they *only excite reverse peristalsis.*

Of all the enemata employed, from milk and molasses to kerosene oil, none have proved of constant value. In my own experience, alum—1 dram to the pint—has seemed to be of some service every time it was used.

In the treatment of tympanites and hiccough, the giving of carminatives, such as peppermint, Hoffman's anodyne, turpentine, and oil of wintergreen should never be permitted. These drugs should be relegated to the family medicine closet and never allowed to enter a serious situation of this nature. Their use is irrational and wholly futile.

Gastric lavage affords considerable relief. The hypodermic administration of physostigmin (eserin) has always seemed to me to be of benefit whenever it was used. This drug must be pushed to its physiologic limit.

Whether the demonstrations of Crile or the experiments of Henderson have proved the nature of shock or not, at least they have made it clear that the hypodermic medication usually indulged in at this time is foolish.

To employ nitroglycerin, digitalin, strychnin, ether, whisky, musk and camphorated oil indifferently, with an idea of helping the patient who is suffering from surgical shock, is simply shocking.

The person who indulges in this spectacular therapy has little conception of the physiologic discord with which he is contending, and less notion of the action of his drugs. To attempt to stimulate an already exhausted vasomotor center with an excitant like strychnin or a vasodilator like nitroglycerin is comic medicine.

The only saving feature of the whole performance is the fact that the usual hypodermic tablet is such an insufficient dose that it has little power for harm.

Oxygen, salt solution and epinephrin are the only chemical agents that have a legitimate excuse for being used in this emergency. Other measures, of course, are of service, but these are posture tongue traction, compression of the limbs, and heat.

Salt solution can be used to excess, let it not be forgotten, although Mummery[3] has shown that salt solution has the power of transporting oxygen to the tissues, a state of hydremia should not be produced.

It is better to use conservative measures such as constriction of the extremities, than to flood the organism with water. Thiers has shown the advantage of using a combination of salts, sodium chlorid, calcium chlorid, and potassium chlorid, rather than the usual sodium chlorid solution.

In simple collapse no drugs are indicated. Here the physiologic balance of the vasomotor system will adjust itself, if given time. Where this fall in blood-pressure is due to moderate hemorrhage, it is probably a conservative action tending to produce hemostasis and coagulation.

---

[3] Mummery: Lancet, London, 1905, i, 696, 776, 846; ii, 780.

Our forefathers, in performing venesection, nearly always bled the patient until he fainted. I have frequently abstracted a pint or a quart of blood, in conditions that seemed to warrant it, and had my patients faint, lose the radial pulse, sweat, have their heart-sounds become almost inaudible, though the carotids could be seen beating slowly and rhythmically, the respiration unhurried. I have not been alarmed but, giving them due time, watched the return of vascular balance unaided and unimpeded by medication.

There are other conditions, however, arising postoperatively that require chemical therapy. One of the most frequent situations comes from infections of the urinary tract, incident to catheterization.

It is lamentably frequent that one undergoes a surgical operation for one pathologic feature, and develops another in its place. Many women, taking advantage of modern surgery to gain relief from some pelvic disease, come from the hospital with an unrecognized cystitis. Later they have an ascending infection and a pus kidney.

In every case demanding catheterization, hexamethylenamin should be given in sufficient doses, well diluted with water, to act as a prophylactic against this ubiquitous pest.

The experiments of Crowe[4] at Johns Hopkins Hospital, relative to the inhibitory action of hexamethylenamin on infections of the meninges, gall-bladder and serous cavities in general, should be sufficient to prompt the employment of this valuable drug in lesions or operative maneuvers involving the brain, spinal cord, gall-bladder, joints and urinary tract.

Many cases of supposed post-partum infection really are acute renal infections from a latent cystitis, or traumatic ureteritis. This is the frequent and unrecognized cause of puerperal fever.

It would be a highly salutary routine to give hexamethylenamin in every case of confinement, since 20 per cent. of all pregnant women present infected urinary tracts to some degree.

And more might be said on the subject, were it not that I have said too much already, and less would have been said were I wiser than I am.

But the burden of my story is this—that we do a lot of stupid things through thoughtless imitation of other men; that we should try to have a reason for what we do; that we should be governed more by the well-proved experiments of modern research, and that simplicity should be the dominant element in postoperative treatment.

401 Third Street.

Medical Research.—There is no realm, however, in which the deep satisfaction of seeing discovery applied to human service, is more likely to be experienced than in the realm of medical research. Consider how great must have been the joy of Pasteur and of Lister when they realized that the consequences of their investigations must lessen forever plague and pestilence and pain in men, and in the lower animals as well, and must permanently remove much of the blind struggle against mysterious agencies of disease and death. The letter which Walter Reed wrote to his wife on New Year's eve, 1900, at the end of his experiments on the transmission of yellow fever, tells something of the joy of such service—"The prayer that has been mine for twenty years," he concludes, "that I might be permitted in some way or at some time to do something to alleviate human suffering, has been granted! A thousand happy new years." And a thousand happy new years there will be for thousands of men and women and children, because of that one research in Cuba.—Cannon in *Science*.

A CLINICAL STUDY OF MOBILITY OF THE HEART *

DUDLEY FULTON, MD.
Assistant Professor of Theory and Practice of Medicine, University of California (Los Angeles Department); Attending Physician to the Los Angeles County Hospital
LOS ANGELES

It has long been known from bedside study, and more recently from the use of the x-rays, that the heart occupies no fixed position in the thorax. The heart is held suspended by its large vessels and is in intimate relation with the walls of the thorax, the mediastinal tissues, the lungs, and the diaphragm. It is evident that the position of the heart may, therefore, be modified by abnormalities of any of the supporting structures, as mediastinal tumors, pleural effusion, pulmonary disease, particularly deformities resulting from tuberculosis, and by abdominal conditions which modify the position of the diaphragm, such as enlargement of the liver, ascites, intra-abdominal growths, and pregnancy. The physiologic factors which modify the position of the heart are, (1) respiration and (2) changes in the position of the body. I have concerned myself only with the latter in this study. Other causes of cardiac displacement will be mentioned only incidentally.

Cherchevsky[1] first called attention to abnormal mobility of the heart. In forty cases studied to determine the effect of changes in position of the body on the apex-beat, he found the mobility to be normally from 1.5 to 3 cm. In nineteen cases it varied from 4 to 7.5 cm.; there was slight mobility in six cases and no movability in fifteen. He considered a range of mobility exceeding 3 cm. as abnormal. In arteriosclerosis, mobility was greatly diminished or absent.

Rumpf[2] concluded from a similar study that the absolute as well as the relative heart-dulness is normally movable about 2 cm. to the left in the left lateral position, and 1.5 cm. to the right in the right lateral position. In many cases the apex-beat remained in the same place, but it often showed a displacement of 2 cm. in a change of posture. Rumpf described five cases, in which the mobility of the heart toward either side amounted to 4 cm., which he designated as "movable heart."

Pick[3] examined 1,000 healthy persons. The majority showed no perceptible difference in the position of the apex-beat and in the percussion sound in different postures of the body. There was slight lateral mobility to the left on assuming a left-sided position in 60 per cent. of the cases, and the apex-beat moved from 1.5 to 2 cm. He described seven cases of movable heart, in which the apex-beat was displaced 4 to 6 cm. to the left.

Hoffman[4] found that the various grades of mobility of the heart were easily recognized by means of x-rays, and concluded that marked movability is of considerable importance to the state of health.

Schmidt[5] concluded that movable heart is often associated with cardiac neurasthenia.

Leusser[6] described several cases of movable heart and considered a displacement of the apex-beat of 3 cm. or more, to the left in the left lateral position, as abnormal.

Rummo,[7] in addition to increased mobility of the heart, described a condition in which there was sagging of the heart from its normal position over the diaphragm, due to relaxation of its supports, and introduced the term to such cases as "cardioptosis." There was no necessary relationship between cardioptosis and enteroptosis. He found both a partial and a complete ptosis, where the heart rests entirely on the diaphragm.

Braun[8] maintains that cardioptosis should be differentiated from movable heart. He does not consider the latter a disease, nor does he think there is justification for attributing neurasthenic heart symptoms to increased mobility of the heart.

Einhorn[9] found cardioptosis in 2.4 per cent. of 926 cases, eighteen men and four women. In the cases of cardioptosis he found it associated with increased mobility of the heart in a number of cases. He regards nervous disturbance of the heart, palpitation, vertigo, and occasionally inability to lie on the left side, as due to cardioptosis. In his opinion, cardioptosis is a distinct clinical entity, equally with enteroptosis.

Hunter[10] described a case of paroxysmal tachycardia and arhythmia with an unduly movable heart. The movability of the heart amounted to 2 inches with change of position from one lateral posture to the other. He was unable to determine that change of posture influenced the paroxysms of tachycardia.

Elliott[11] recently studied the movability of the heart and aorta in health, as evidenced by radiographs taken in unusual positions. That the heart is fairly movable in health and that it may be forced into unusual positions by abnormal physical means is generally understood, but that it is as freely movable as it is, and that its mobility may be made to assist in the interpretation, or may lead to misinterpretation of radiographic findings, unless taken into consideration, has not been sufficiently recognized. A radiograph taken with the patient lying on the right side, respirations at rest, shows that the heart is largely moved to the right of the vertebral column. Similarly, with the patient lying on the left side, respirations at rest, the entire heart shadow is carried to the left, leaving the right border of the vertebral column free and unaffected by the heart-shadow. With the patient lying on the right side, the aorta casts a shadow which extends 4 cm. to the right of the vertebral column, whereas with the patient lying on the left side, the shadow cast by the aorta does not appear to the right of the vertebral edge at all.

Krehl[12] found that the position of the heart changes with that of the body and that the apex-beat is often found to be displaced to the left a few centimeters when the individual lies on the left side. In some cases, however, displacement was so great that the term "wandering heart" was justifiable. In the right lateral position, the apex-beat in healthy individuals either remains unaffected or is displaced only by very little to the right. The change from the horizontal to the vertical position, and vice versa, has no appreciable effect on the apex-beat. Krehl considers that extreme mobility of the heart is due to great loss of intrathoracic fat (starvation cures, tuberculosis) and that in these cases the cardiac displacement causes more or less distress when the patient lies on his side, possibly on account of contraction or kinking of the large vessels.

Determann[13] considered that in nervous persons abnormal mobility of the heart appears to be not uncommon and causes subjective cardiac symptoms. A comparison with movable kidney naturally suggested itself.

Hoffman[14] states that when the position of the diaphragm is high and the heart is abnormally movable so that the larger portion of its area comes in contact with the chest-wall, dilatation may be simulated. He believes that many cases of so-called cardiac dilatation are in reality only examples of this condition. Error can be avoided by testing the mobility of this organ.

Dietlen[15] and Moritz[16] have made extensive orthodiagraphic studies of the size and position of the heart under normal and pathologic conditions. Conner,[17] recently summarizing some of their many interesting facts on this subject, states: 1. With a change from the recumbent to the erect position, there is a distinct sinking of the heart from 2 to 4 cm., corresponding to the lower position of the diaphragm and liver, and that with this the heart assumes a more nearly vertical position while the width of the shadow is considerably lessened. 2. In old age there is regularly a lower level of the diaphragm and a correspondingly lower position of the heart, but in this case the organ, instead of having a more vertical position than usually occupied, was more nearly transverse. The explanation of this is probably to be found in the relaxation of the attachments of the great vessels, by which the heart is held in position. 3. In women the position of the heart is on the average an intercostal space higher than in men. 4. In asthma and emphysema there is a marked sinking of the diaphragm and heart, and to this fact often, more than to the overlapping of the heart by the voluminous lungs, is to be ascribed the great diminution of the heart sounds in the second intercostal space and the low position of cardiac dulness.

The present contribution to this subject is the result of a study of 193 cases. Of this number, forty-nine were apparently healthy. The remaining 144 were private patients or routine cases studied in my wards at the Los Angeles County Hospital.

In studying the movability of the heart in different positions of the patient, the absolute or superficial cardiac dulness was used and determined by feeble percussion. In determining the change of the apex-beat in different postures, the usual point of maximum intensity of the apex-beat was ignored. That point of the heart coming in contact with the palpating finger farthest downward and to the left was considered the true apex.

The conclusions obtained were the result of a second examination, or were controlled by two examiners, so that a fair degree of accuracy may be assumed. In all cases in which there was doubt as to the exact position of the apex-beat or of the border of cardiac dulness, opinion was suspended and these do not enter into the ultimate findings.

[17] Conner: The Clinical Study of Heart Cases, Am. Jour. Med. Sc., June, 1908, p. 790.

One of the most striking facts observed was the discrepancy between the amount of displacement of the apex-beat and that of the cardiac dulness in the change of position of the patient. The change in the apex-beat amounted in some cases to 5 cm. or 6 cm., while that of the cardiac border of dulness was only 2 cm. or 3 cm., and vice versa, so that, as far as our experience teaches us, these two factors are not always as constant as one might expect them to be. This may be due to the fact that in changing the position of the body there occurs a twisting of the heart on its long axis, thus making considerable alteration in that portion of the heart which comes in contact with the chest-wall as the apex-beat.

In the 193 cases there were nine in which there was total displacement of the heart downward, the so-called cardioptosis of Rummo. In seven of these there were clinical signs of atheroma of the aorta. The low position of the apex in these cases on first impression suggested aortic valve disease until the cardioptosis was discovered, which to me emphasizes the importance of invariably testing the mobility and position of the heart before assuming from an abnormal position of the apex-beat that dilatation or hypertrophy is present. Close examination in all of these cases of cardioptosis showed that the heart *en masse* was displaced downward from one to two interspaces.

Of the forty-nine persons in health, consisting largely of high school students, the average displacement of the apex-beat from the dorsal position to the left lateral position was 3.02 cm. to the left, while the right border of cardiac dulness changed only 1.04 cm. The greatest change in the apex-beat was 5 cm. and that of cardiac dulness 8 cm.

The smallest change in the position of the apex-beat was 2 cm. and that of cardiac dulness was in patient M. K., aged 15, apparently well, in whom there was no change in the movability of the heart from the dorsal to the left lateral.

Of the 144 patients selected routinely, suffering from various diseases, the average change in the apex-beat with the patient changing from the right lateral to the left lateral position, was 3.9 cm., the change in cardiac dulness, 2.7 cm. The maximum displacement of the apex-beat was 14 cm. in a case of pulmonary tuberculosis. In another tuberculous subject the displacement amounted to 10.5 cm.; in another, 13.5 cm. In one case of mitral regurgitation the displacement of the apex amounted to 9 cm., in another to 7.5 cm., and in still another to 8.5 cm. In other patients with the same diagnosis, however, the mobility of the apex was normal or diminished, so that the movability of the heart in these conditions was by no means characteristic. The greatest mobility of the cardiac dulness was 12.8 cm., in a case of pulmonary tuberculosis. In a second case of tuberculosis it was 12 cm. In the cases of cardiac lesions, twenty-five in number, excluding six cases of pericarditis with adhesions, the displacement of the apex-beat was 3.6 cm., and the change in the cardiac dulness with change in position of the patient from the right lateral to the left lateral was 3.3 cm. No differences in the displacement of the heart were observed in mitral and in aortic valvular lesions. In the six cases clinically diagnosed as pericarditis, two being confirmed at autopsy, with adhesion of the outer pericardium to surrounding structures, there was fixation of the heart: no change in either the position of the apex-beat or cardiac dulness occurred when the patient changed from the right to the left lateral postures.

The impressions from this study, imperfect as it is, are, first, that the determination of the movability of the heart is of considerable value in the differential diagnosis of cardiac dilatation, and that before assuming that the heart is dilated to the right or to the left, the movability of the heart should always be determined.

Secondly, the immobility or fixation of the heart should always arouse the suspicion of adhesion of the pericardium to neighboring organs. There is probably no serious heart lesion diagnosticated less frequently, clinically, than pericarditis with adhesions. Since systolic retraction of the interspaces and other signs of this condition are so frequently absent, it seems that it would be well to emphasize immobility or fixation of the heart as one of the signs of pericardial adhesions.

My thanks are due Drs. J. W. Nevius and J. W. Bardill for assistance in the production of this paper.

THE BACTERIOLOGY OF THE EAR *

JESSIE B. HUDSON, M.D.
IOWA CITY, IA.

Determining the variety of bacteria present in disease of the ear is an aid to prognosis and warns us of possible complications. Single infections are usually acute, while mixed infections are apt to become chronic. There are very few cases of sinus thrombosis reported as due to pneumococci, but streptococcus sinus thrombosis is of common occurrence. Streptococci also frequently cause brain abscess and may involve important structures by necrosis, or may cause a fatal septicema. Hence, it is important to know whether these organisms are present. Streptococci and pneumococci appear to be the most frequent cause of otitis and mastoiditis. Staphylococci are found in a large percentage of chronic cases, seldom in pure culture.

Most investigators do not consider infection with staphylococci likely to be serious, but operation is necessary in about half the cases of infection with *Streptococcus pyogenes* or *Streptococcus mucosus*. If meningococci are found we know the patient has, or is likely to have, meningitis.

Examination of ear discharges is important in cases infected with diphtheria bacilli in order that proper precautions may be taken to prevent the spread of the disease. Newsholme (1904) reports a case of infection with diphtheria from a case of otorrhea—a pure culture of diphtheria bacilli being obtained from the ear discharge. Graham-Smith (1904) reports five cases, infected with virulent Klebs-Loeffler bacilli from contact with a patient having otorrhea. Several others have obtained virulent diphtheria germs from the ear. Diphtheria-like bacilli are often found in ear cases; a small percentage of these are virulent. Nuttall and Graham-Smith found 10 per cent. virulent. It is necessary to make cultural tests and animal inoculations before making a positive diagnosis of diphtheria.

---

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

In many reported cases, examination for bacteria was made only after puncture of the ear-drum. It is very difficult to sterilize the external auditory canal and drum-head so as to get uncontaminated cultures from the discharge. Leutert was the first to take cultures at the time of operation. He found streptococci predominating. In chronic cases staphylococci were most numerous. He thinks sinus thrombosis and brain abscess caused almost exclusively by streptococci. Newman and Rutten, in an article on "Etiology of Acute Otitis Media," come to practically the same conclusions. Libman found streptococci predominating. Barnhill and Wales report two-thirds of complications due to streptococci. McKenna says that *Streptococcus mucosus* is frequently found in otitis media, which explains its relative frequency as a cause of acute meningitis. Richardson mentions it as a cause of mastoid disease. Bacon thinks that most cases of acute otitis media are due to the influenza bacillus.

Infection may reach the middle ear through a ruptured drum-head, through the petrosquamosal fissure in the infant, through defects in the tegmen covered over with fibrous tissue, or in fracture of the temporal bone. It may travel along the nerve sheaths or blood-vessels, or the blood may carry infection to the ear. These cases, however, are rare. Microorganisms most frequently reach the ear from the nose and throat through the Eustachian tube. The chief predisposing factor is an inflammation of the nasopharynx or nasopharyngeal obstruction. Acute infection in the middle ear, with inefficient drainage or lack of proper treatment, is one of the most frequent causes of mastoiditis. A lowered vitality, exposure to wet and cold, and also certain constitutional diseases act as predisposing factors.

The question as to whether bacteria are present in the normal mastoid antrum is an important one. If they are present, then some relatively unimportant predisposing cause, as exposure to wet and cold, or loss of vitality from general or local causes, will give these bacteria an opportunity to develop and cause pathologic changes and loss of function, to a greater or less extent, and possibly serious complications.

Many investigators claim that the normal tympanic cavity and mastoid antrum contain pathogenic germs, few in number, which become active under favorable conditions. Others are just as positive that no pathogenic germs are present. The tympanum communicates with the Eustachian tube in front and with the mastoid antrum and cells behind. Since the Eustachian tube admits air to the middle ear, there seems to be no reason why it should not also admit bacteria from the throat.

A number of cases have been reported in which the mastoid was primarily involved. Two to 4 per cent. of typhoid patients have ear complications, the mastoid often being involved. Various organisms are found—staphylococci, streptococci, diplococci, colon bacilli, etc., thus apparently showing that a lowered vitality is the predisposing factor and that bacteria are already present.

In the following twenty-one cases, I have collected the material at the time of operation, made cultures and isolated and identified the bacteria. The material for examination was collected in sterile Petri dishes, and was then transferred to flasks containing 100 c.c. of sterile broth; an agar culture was also made by pouring agar on the material remaining in the Petri dish. These were incubated for twenty-four hours at 37 C. and then agar and gelatin plates were made. The plates were incubated from twenty-four to forty-eight hours. The colonies were then examined—methylene-blue and Gram stains being made, also hanging drops to determine motility, after which cultures were made from the different colonies on the various sugar media, on gelatin, blood-serum, milk, litmus milk, potato, and glucose and lactose bouillon. Where necessary, smears were stained for spores, capsules and flagella.

REPORT OF CASES

Following are given the synopses of twenty-one cases as taken from the history sheets:

Case 1.—N. G., aged 19. September 29, complains of a discharge from the left ear, a roaring sound in the ear, and constant headache. Trouble started four years ago and has gradually become worse. Complains of a slight sore throat. At first, ear discharged only when lying on left side. No pain at that time. Complains of pain only when she catches cold in ear. Discharge night and day. Cannot hear very well with left ear. Whooping-cough when 2 years old and measles at 12. Perfectly well at present except for ear trouble. In left ear bone, conduction is better than air.

Diagnosis.—Chronic discharge from left ear, chronic mastoiditis left.

Operation.—October 1, radical mastoid—left.

Bacteriology.—Staphylococci and an unknown bacillus in left tympanic cavity. Streptococci found in left ear, December 6.

November 19, double suturing of left mastoid wound. Discharged February 9.

October 5, ear began discharging last Thursday and has been discharging ever since. March 8, left ear has been discharging for last two weeks. Sense of fulness in left side of head. Dull ache back of left ear.

Result.—Complete recovery. No improvement in hearing in left ear.

Case 2.—E. T., aged 13. November 3, complains of ear-ache in left ear. Ear has discharged for many years. Some impairment of hearing. Aches only in winter. Trouble starts as soon as cold weather sets in. Discharge and ear-ache whenever patient catches cold. Past history not known, patient being an adopted child.

Examination.—Bone and air conduction equal in left. Drum-head badly scarred.

Diagnosis.—Adenoids and diseased tonsils, chronic otorrhea—left.

Operation.—November 5, left radical mastoid with dura exposed.

Bacteriology.—Streptococci, *Staphylococcus aureus* and *albus*.

Plastic Operation.—November 19.

An autogenous vaccine was prepared and given every seven days in the following doses:

First—	
Streptococci	5,000,000
Staph. alb.	100,000,000
Staph. aureus	100,000,000
Second—	
Streptococci	10,000,000
Staph. alb.	200,000,000
Staph. aureus	200,000,000
Third—	
Streptococci	15,000,000
Staph. alb.	400,000,000
Staph. aureus	400,000,000
Fourth—	
Streptococci	20,000,000
Staph. alb.	600,000,000
Staph. aureus	600,000,000
Fifth—	
Strept.	30,000,000
Staph. alb.	80,000,000
Staph. aureus	800,000,000

Sixth—Same as Fifth.

Result.—Complete recovery; patient gained in weight, and health much improved.

Case 3.—H., schoolboy.

Diagnosis.—July 17, serous catarrh middle ear.

Operation.—Simple mastoid—left.

Bacteriology.—Staphylococci.

Operation.—August 4, adenoids and tonsils removed.

Result.—Complete recovery.

CASE 4.—R. B., aged 2.

Diagnosis.—February 23, acute mastoiditis, both sides.

Operation.—February 25, right simple mastoid.

Bacteriology.—Streptococci. March 6, diphtheria bacilli found in culture from right ear. The diphtheria bacilli were tested and found to be virulent.

Operations.—March 8, left simple mastoid. Sutured right. April 1, sutured left mastoid.

Discharged May 14.

CASE 5.—S. C., aged 22. April 24, complains of a growth on right mastoid. Commenced eight years ago. At times, patient says, it seems to puff up and then go down again. There has been no pain and no discharge. Never dizzy that she can remember. At times the growth is somewhat painful when pressure is made.

Diagnosis.—Mastoiditis.

Operation.—April 24, simple mastoid.

Pathology.—Enlarged glands over mastoid region, tip of mastoid somewhat diseased. Antrum normal. Laboratory report: One of the glands was sectioned and found to be lymphoid tissue, somewhat inflamed. Culture from the antrum showed numerous bacteria, including *Staphylococcus albus.*

Result.—Complete recovery.

CASE 6.—N. N., complains of loss of hearing and discharging ear. About two years ago noticed hearing was affected. The discharge began about six months ago.

Operation.—May 20, radical mastoid—right.

Pathology.—Dura exposed over tympanic cavity. Extensive necrosis along posterior wall.

Bacteriology.—Gram-negative streptococci, *Staphylococcus albus.*

Operation.—June 4, sutured right mastoid.

Result.—Complete recovery, hearing normal.

CASE 7.—F. A., aged 8. September 29. Ear trouble began two years ago. Had scarlet fever with diphtheria following. Had tonsils removed when he had diphtheria. Left ear began to discharge then and has been discharging nearly all the time since. Some better the past year. Had ear-ache at times before discharge began. Had to cleanse ear three or four times a day. Odor offensive. Mastoid region painful once in a while. Right ear discharged for a short time after attack. Hearing bad in left ear.

Examination.—Right ear normal. Left ear, high notes normal. Bone conduction better than air. Whisper, one foot; speaking voice, four feet. Perforation of drum-head, discharge from ear.

Diagnosis.—Chronic otorrhea.

Operation.—September 3, radical mastoid.

Pathology.—Necrotic bone removed from middle fossa exposing dura. Attic filled with granulations. Removed hammer. Found many cells about external auditory canal. Necrotic material next dura and pachymeningitis. Surface of dura inflamed, dura not bulging.

Bacteriology.—*Sarcina aurantiacea* and rhodococcus.

Result.—Complete recovery, no improvement in hearing in left ear.

CASE 8.—L. D., aged 17. October. Trouble began in right ear about a year ago, caused by a bad cold. Had severe pain in ear and mastoid tenderness for about a week. Could not hear well with that ear. There was a discharge for a few days at first. Has not discharged since then but has had much pain in ear and back of ear. For the last month pain has been constantly present.

Examination.—Right ear, high notes normal. Air conduction better than bone. Small hemorrhages on lower half of drum-head. Whisper, 15 feet; speaking voice, 40 feet. Caloric test showed labyrinth functionating. Left ear normal.

Operation.—October 7, simple mastoid—right.

Pathology.—Necrosis below antrum and over angle of lateral sinus. All cells inflamed.

Bacteriology.—Sarcina was the only organism found. Patient completely recovered.

CASE 9.—Patient, aged 26. October 29 had had trouble with right ear for thirteen years, since scarlet fever. For the last three months it has been discharging constantly—pain at times.

Examination.—Perforation in drum-head. Right tube open. Ear might get well with packing and inflation. Right ear, whisper 4 inches; speaking voice 20 inches. Left ear, whisper 15 feet; speaking voice, 35 feet.

November 28. Needs radical mastoid.

Operation.—December 1, right radical mastoid.

Pathology.—Exposed lateral sinus at knee; sinus was thickened and covered with granulations. Necrosis down to facial canal; necrosis above and posteriorly. Polyps in tympanic cavity. Facial nerve unaffected after operation.

Bacteriology.—*Staphylococcus aureus.*

Result.—Complete recovery from operation; no improvement in hearing.

CASE 10.—G. R., aged 10. November 9. Complains of ear trouble. Had tonsillitis four weeks ago, and after a few days his left ear began to discharge. Had ear-ache in left ear during his attack of tonsillitis and just before the ear began to discharge. The discharge stopped last Saturday, when he noticed a swelling behind his ear. Says it is not sore unless he presses it. Hearing somewhat impaired. Does not breathe through his nose at night and only a part of the time during the day. Had measles when 8 years old. Past medical history otherwise negative.

Diagnosis.—Acute mastoiditis.

Operation.—November 11, left simple mastoid. Adenoids removed.

Pathology.—Open sinus leading into antrum. Much pus present. Dura not exposed. Parasinus abscess and external dural abscess. Lateral sinus exposed full length.

Result.—Complete recovery.

Bacteriology.—Streptococci.

CASE 11.—H. J., aged 16. November 18. Hurt in a runaway in March. Unconscious three or four hours. Has had trouble back of ear and in back of head since. Both ears discharged some at times since then. Has had paracentesis of left ear-drum once, and of right, three or four times. This relieves pain for a time. Pain begins in back of head and head throbs. Tenderness over right mastoid extending back almost to occipital protuberance since accident. Had vomiting spell just after accident but none since. Headache all the time.

Examination.—Right and left ears normal.

Diagnosis.—Traumatic mastoiditis or periostitis and osteitis.

Operation.—November 2, right simple mastoid. Removal of necrotic bone posterior to mastoid region, exposing lateral sinus and dura.

Pathology.—Circular area of necrotic bone below lateral sinus three and one-half inches posterior to external auditory canal. Extended to dura. Periosteum black over this area. Periosteum peels off with difficulty. Mastoid antrum and cells normal. Posterior emissary vein one inch posterior to mastoid. Lateral sinus exposed. Dura exposed in right occipital region and appears normal.

Bacteriology.—*Staphylococcus albus* and *aureus* and an unknown bacillus found in mastoid antrum.

December 17, ear began to pain and drum was bulging. Paracentesis done. Found only serum. *Staphylococcus albus* found in discharge. January 12. Paracentesis right drum. February 16, discharged—perfectly well.

CASE 12.—R. F., schoolboy. November 1. Says his ears have discharged ever since he can remember. No other history obtainable.

Examination.—Right ear, yellowish discharge. Perforated drum-head. High notes normal. Bone conduction better than air. Whisper 3 feet; speaking voice 10 feet. Tests show labyrinth functionating. Left ear—yellowish discharge. Perforated drum-head. High notes normal. Bone conduction better than air. Whisper, 15 feet; speaking voice, 30 feet. Tests show labyrinth functionating.

Diagnosis.—Double chronic otorrhea.

Operations.—November 4, right antromeatal. Adenoids removed. November 11, left radical mastoid. November 18, plastic operation.

Pathology.—All mastoid cells necrotic. Lateral sinus not exposed. Pus in attic. Exposed dura. Pachymeningitis.

Bacteriology.—Pneumobacillus.

Pathology.—Tip necrotic. Necrosis anterior and external to facial—very extensive. Much necrosis at opening of Eustachian tube. One arm of incus gone. Malleus in fair shape. Cerebellum exposed just under lateral sinus.

Bacteriology.—Pneumobacillus.

January 2, left ear well; right improving. No improvement in hearing in left; about two-thirds normal in right.

Case 13.—L. C., aged 17. November 26. Left ear discharged when a baby. No discharge after that for six or seven years. Since then, whenever he catches cold the ear discharges. Discharge yellowish, has bad odor. No pain in ear. No pain or swelling over mastoid region. Thinks he cannot hear with this ear.

Examination.—Right ear, air conduction better than bone. High notes cut down. Whisper, 15 feet; speaking voice, 40 feet. Left ear, high notes cut down. Bone conduction better than air. Whisper, 6 inches; speaking voice, 25 feet. Tests showed labyrinth functioning. Perforation of drum the size of pea.

Diagnosis.—Chronic otorrhea.

Operation.—December 2, left radical mastoid.

Pathology.—Complete necrosis of mastoid. Posterior fossa exposed. Exposed dura. Shiny material in antrum.

Bacteriology.—*Staphylococcus aureus* and *Micrococcus tetragenus.*

Patient developed slight facial paralysis December 4, which lasted until December 13. Went home before ear was well. Not known whether he had further trouble.

Case 14.—W. W., aged 17. November 5. Had tonsils removed ten years ago. Two years ago adenoids removed. Since that operation, ears have been discharging almost constantly. Turbinates large and fibrous. Remains of tonsils infected. Left, voice, 8 inches; right, whisper, 10 feet. Advised to have nose repaired first, and at same time have ear treated twice a day. Later, if necessary, mastoid operation.

October 7, acute tonsillitis. October 19, left inferior turbinate trimmed. Has a very high arch with an overhanging bite. Arch should be widened. November 16, right inferior turbinate trimmed. November 26, paracentesis left drum-head.

Operation.—December 19, left meatomastoid. Dura exposed in middle fossa; lateral sinus exposed and whole mastoid necrotic.

Bacteriology.—Colon bacillus and *Bacillus diphtheriæ.*

Result.—Patient well, no further trouble with ear, hearing about one-fourth of normal.

Case 15.—E. G., aged 16, December 13, complains of discharging ears. Puffing noise constantly in right ear. Says hearing is impaired in right ear. Normal in left. When a baby, had discharge from both ears; does not remember how long it lasted. Seven years ago one discharged, does not remember which one or how long it lasted. Last April he had mumps on both sides and two weeks later measles. Ears both began to discharge when the patient had mumps. Left one discharged for two months, right one ever since—occasionally stopping for a day or two at a time. Some pain below right ear and in front of mastoid. No pain or swelling behind ear. Discharge was of a yellowish color, profuse and had an offensive odor. Has been treated for past three months.

Physical Examination.—Pus in external meatus. Drum-head thickened. High notes normal Air conduction better than bone. Whisper, 2 feet; speaking voice, 12 feet. Test showed labyrinth functionating. Adenoids present. Punctured right and left nasal antrum and found a small amount of old pus in left.

Diagnosis.—Mastoiditis, right.

Operation.—December 16, right simple mastoid, also adenoids removed.

Pathology.—Eburnated bone in cortex. Antrum and neighboring cells filled with pus.

Bacteriology—Pneumobacillus.

December 30, taken to isolation ward for erysipelas beginning about 1 inch anterior to right ear. Began December 28. January 2, had a little tenderness over tip of left mastoid. January 3, swelling on left side of neck just below mastoid.

Operation.—January 12, paracentesis—right. Discharged. March 1, comes back because her right ear is discharging—started two weeks ago. Discharged April 7. Ears well, hearing about one-half normal in right ear.

Case 16.—A. P., aged 16. December 15. Was slow in learning to talk. At times hears fairly well. When he takes cold, hearing is affected. To-day hears loud voice at 6 inches only. Sleeps with mouth open.

Examination.—Left drum-head scarred and retracted. Right external canal filled with pus. Right ear, loud voice, 6 inches; lef tear, cannot hear speaking voice. Tonsils and adenoids should be removed. Needs a meatomastoid operation.

Operation.—December 16, radical mastoid.

Bacteriology.—Colon bacillus.

Operation.—December 28, adenoids removed.

Result.—Complete recovery from operation; hearing in right ear about one-half normal.

Case 17.—E. V., aged 15, January 7. Ear trouble began one week ago last Monday. Left ear began to ache, continued to ache for a couple of days, and then began to discharge. Has been discharging ever since and is painful most of the time. Mastoid region swollen after ear began to discharge. Had influenza and sore throat about one week before ear trouble began. Says she had ear-ache a great deal about eight years ago; does not remember which ear or whether it discharged any. Breathes through mouth day and night. When she catches cold has a dull pain over right antrum. Had ulcerated tooth on right side above one or two years ago. Nose constantly discharges—yellowish—no odor.

Physical Examination.—Right ear normal. Left ear, perforation of drum-head with discharge of pus. Drum-head bulging. Tenderness over mastoid. Pain in ear most of the time. High notes normal. Bone conduction better than air.

Diagnosis.—Left otorrhea and mastoiditis.

Operations.—January 7, paracentesis left ear-drum. January 13, left simple mastoid.

Pathology.—Mastoid cells small and all filled with pus: Not much necrosis. Exposed lateral sinus at knee.

Bacteriology.—Streptococci, some of them Gram-negative. *Micrococcus catarrhalis.* Hay bacillus.

Discharged February 15. Ears normal.

Case 18.—M. G., aged 16. January 16. Has had trouble in right ear as long as she can remember. If she catches cold, she has ear-ache. Three or four years ago had ear-ache in right ear a great deal. One year ago, right ear discharged for two or three weeks. Discharge was purulent. Since then no discharge until middle of December, when she had measles. December 26, had a severe ear-ache; discharge began and has continued ever since, stopping at times for a day or two. Ear has been very painful; was swollen over mastoid region a part of the time. Ear and mastoid region have been massaged by an osteopath. Says she had tonsillitis several years ago, also on left side, when she had measles. Has had sore throat occasionally and could open her mouth only one-half inch.

Physical Examination.—Tenderness over mastoid. Pulsating ear-drum. Abscess under temporal muscle. High notes normal. Bone conduction better than air conduction.

Diagnosis.—Mastoiditis—right. Probably abscess under temporal muscle.

Operation.—January 20, right simple mastoid. Paracentesis right ear-drum.

Pathology.—Abscess in temporal muscle. Pus in mastoid antrum. Exposed lateral sinus. Badly necrosed bone extending to dura. Has pachymeningitis and perisinus abscess, with inflammation of walls of sinus. Dead bone lying next to brain and attached to dura. Bone between temporosphenoidal lobe and sinus all rotten. Granulations on lateral sinus. No evidence of leptomeningitis or local brain abscess. Dura not tense.

Bacteriology.—Staphylococci and Gram-negative streptococci.

February 10, sutured right mastoid. February 26, patient came back for examination; was to come twice a week for treatment. April 4, discharged—ear well.

May 11. Has come back for treatment of other ear. Hearing improved.

Case 19.—L. R., aged 19. January 26. Right ear began aching January 25. Discharge began January 26; purulent and bloody. Soreness over mastoid; left ear aching some at present.

Operation.—February 23, simple mastoid, right. Results good.

Pathology.—All mastoid cells necrotic; dura not exposed.

Bacteriology.—*Streptococcus* and *Staphylococcus albus.*

Results.—May 13. Discharged, complete recovery.

Case 20.—Mrs. L., aged 41. February 1. Sunday morning had an ear-ache. Right ear pains; has roaring in ears; hears water running, katydids, etc.

Examination.—Left drum-head retracted; pain on pressure over tip of right mastoid. Right ear, loud voice 4 feet; left, whisper 3 feet.

Diagnosis.—Right ear, abscess with mastoid involvement. Had ulcerated upper molar on right side. Just above second molar on right side is a discharging sinus. Has had discharge from nose before. Exploratory puncture of right antrum; lots of pus.

Diagnosis.—Empyema of antrum of Highmore secondary to necrotic tooth.

Operation.—February 3, right simple mastoid. Infected with gas-producing organism; gas bubbled up when antrum was approached and also when ear-drum was cut. Pain in antrum.

Bacteriology.—*Streptococci, Micrococcus aerogenes capsulatus* and *B. subtilis.*

Operation.—Right radical antrum, middle and third molars removed. With the third there came away a part of the alveolar process, which was necrotic, and left an opening into the antrum. Antrum was filled with polyps.

March 24, canal has been dry for several days.

May 2, mastoid and antrum well. Return for closure of opening between antrum and mouth. Result normal.

Case 21.—M. G. March 3. Last Wednesday had a sore throat and right ear started to ache, is still aching. Has a sense of fullness in right side of head. Mastoid region very tender. Glands at angle of jaw very painful. Six weeks previously had appendicitis and was operated on. A few days later temperature rose to 105 F., and examination showed an abscess at site of operation. Bacteriologic examination of the pus showed streptococci. She recovered from this and was about to be discharged from the hospital when the ear trouble began.

Ear discharged when she was a very small child. Also discharged last year. Tonsils become inflamed whenever she catches cold. Are inflamed now. Cannot see very well; wears glasses. Has headache, photophobia; eyes water a great deal.

Left ear normal. Right ear, drum head bulging and a little red. Slight tenderness at mastoid tip. Bone conduction better than air conduction. High notes normal; whisper, 10 inches; speaking voice, 6 feet.

Operations.—March 3, paracentesis, right ear. March 10, right simple mastoid.

Pathology.—Necrosis of antrum; dura over middle fossa and lateral sinus exposed.' Granulations over middle fossa on dura.

Bacteriology.—Gram-negative streptococci.

This case is particularly interesting from the fact that the ear infection followed so soon after the appendicular abscess and was caused by the same organism. The infection was evidently carried by the blood. Recovery complete.

In two of these cases the mastoid antrum was normal and pathogenic bacteria were found. In one other case not included in this series, I found pathogenic bacteria in the normal antrum.

There were thirteen chronic cases and six acute cases. In seven chronic cases, staphylococci were found. In only two cases were they the only organism found. In three of the chronic cases streptococci were present, but not in pure culture. In two chronic cases pneumobacilli were found in pure culture. Colon bacilli were found in two chronic cases, once in pure culture, once with *Bacillus diphtheriæ.*

Diphtheria bacilli occurred as a secondary infection in one acute case. In the six acute cases streptococci were found, three times in pure culture. In one acute case Gram-negative streptococci were the only germs found. Staphylococci were found in one acute case—not in pure culture. *Micrococcus aerogenes capsulatus, Micrococcus catarrhalis* and *B. subtilis* were found in mixed infections. In many cases no history was obtainable as to the cause of the disease. In two cases ear trouble followed scarlet fever; in one mumps and measles; in one influenza; in one tonsillitis; in one removal of adenoids; in one the disease followed empyema of the antrum of Highmore, secondary to a necrotic tooth. One was made worse by an attack of measles. Five cases were aggravated by taking cold. In most of the chronic cases and in one acute case, necrosis was extensive. It did not appear to be worse where streptococci were present.

SUMMARY AND CONCLUSIONS

1. Bacteria are normally present in the mastoid antrum. This is to be expected since there is a continuous passage from the throat through the Eustachian tube and middle ear to the antrum.
2. Mastoiditis is caused by a variety of organisms. Those found in my cases were *Staphylococcus, Streptococcus, Micrococcus catarrhalis,* diphtheria bacillus, *B. coli communis,* pneumobacillus, *B. aerogenes capsulatus, Micrococcus tetragenus,* sarcina, and *B. subtilis.*
3. In three cases of ear disease Gram-negative streptococci were found.
4. The few patients who were treated with vaccines after operation were remarkedly benefited.

I wish to thank Dr. Dean for the opportunity of studying these cases, also for the suggestions he has given me in my work, and for the use of his private library.

207 North Capitol Street.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

CALCIUM PHENOLSULPHONATE—Calcii phenolsulphonas—Calcium Sulphocarbolate.—Calcium 1,3-phenolsulphonate. $[C_6H_4(OH)SO_3]_2Ca=Ca(C_6H_5O_4S)_2$ is the neutral calcium salt of para-phenolsulphonic acid.

Calcium phenolsulphonate occurs as a white, or faintly pinkish-white, almost odorless powder, having an astringent, bitter taste. At high temperatures the salt chars, emits inflammable vapors having an odor of phenol, and finally leaves a residue of calcium sulphate.

The salt is easily soluble in water and in alcohol.

An aqueous solution of the salt (1-100) should assume a pale violet color on the addition of ferric chloride test solution.

If 5 Gm. of the salt be percolated with 25 Cc. of ether in a small filter, the solvent allowed to evaporate spontaneously and the residue, if any, dissolved in 5 Cc. of water, the solution should

Operations.—November 4, right antromeatal. Adenoids removed. November 11, left radical mastoid. November 18, plastic operation.

Pathology.—All mastoid cells necrotic. Lateral sinus not exposed. Pus in attic. Exposed dura. Pachymeningitis.

Bacteriology.—Pneumobacillus.

Pathology.—Tip necrotic. Necrosis anterior and external to facial—very extensive. Much necrosis at opening of Eustachian tube. One arm of incus gone. Malleus in fair shape. Cerebellum exposed just under lateral sinus.

Bacteriology.—Pneumobacillus.

January 2, left ear well; right improving. No improvement in hearing in left; about two-thirds normal in right.

CASE 13.—L. C., aged 17. November 26. Left ear discharged when a baby. No discharge after that for six or seven years. Since then, whenever he catches cold the ear discharges. Discharge yellowish, has bad odor. No pain in ear. No pain or swelling over mastoid region. Thinks he cannot hear with this ear.

Examination.—Right ear, air conduction better than bone. High notes cut down. Whisper, 15 feet; speaking voice, 40 feet. Left ear, high notes cut down. Bone conduction better than air. Whisper, 6 inches; speaking voice, 25 feet. Tests showed labyrinth functioning. Perforation of drum the size of pea.

Diagnosis.—Chronic otorrhea.

Operation.—December 2, left radical mastoid.

Pathology.—Complete necrosis of mastoid. Posterior fossa exposed. Exposed dura. Shiny material in antrum.

Bacteriology.—*Staphylococcus aureus* and *Micrococcus tetragenus.*

Patient developed slight facial paralysis December 4, which lasted until December 13. Went home before ear was well. Not known whether he had further trouble.

CASE 14.—W. W., aged 17. November 5. Had tonsils removed ten years ago. Two years ago adenoids removed. Since that operation, ears have been discharging almost constantly. Turbinates large and fibrous. Remains of tonsils infected. Left, voice, 8 inches; right, whisper, 10 feet. Advised to have nose repaired first, and at same time have ear treated twice a day. Later, if necessary, mastoid operation.

October 7, acute tonsillitis. October 19, left inferior turbinate trimmed. Has a very high arch with an overhanging bite. Arch should be widened. November 16, right inferior turbinate trimmed. November 26, paracentesis left drum-head.

Operation.—December 19, left meatomastoid. Dura exposed in middle fossa; lateral sinus exposed and whole mastoid necrotic.

Bacteriology.—Colon bacillus and *Bacillus diphtheriæ.*

Result.—Patient well, no further trouble with ear, hearing about one-fourth of normal.

CASE 15.—E. G., aged 16. December 13, complains of discharging ears. Puffing noise constantly in right ear. Says hearing is impaired in right ear. Normal in left. When a baby, had discharge from both ears; does not remember how long it lasted. Seven years ago one discharged, does not remember which one or how long it lasted. Last April he had mumps on both sides and two weeks later measles. Ears both began to discharge when the patient had mumps. Left one discharged for two months, right one ever since—occasionally stopping for a day or two at a time. Some pain below right ear and in front of mastoid. No pain or swelling behind ear. Discharge was of a yellowish color, profuse and had an offensive odor. Has been treated for past three months.

Physical Examination.—Pus in external meatus. Drum-head thickened. High notes normal Air conduction better than bone. Whisper, 2 feet; speaking voice, 12 feet. Test showed labyrinth functionating. Adenoids present. Punctured right and left nasal antrum and found a small amount of old pus in left.

Diagnosis.—Mastoiditis, right.

Operation.—December 16, right simple mastoid, also adenoids removed.

Pathology.—Eburnated bone in cortex. Antrum and neighboring cells filled with pus.

Bacteriology—Pneumobacillus.

December 30, taken to isolation ward for erysipelas beginning about 1 inch anterior to right ear. Began December 28. January 2, had a little tenderness over tip of left mastoid. January 3, swelling on left side of neck just below mastoid.

Operation.—January 12, paracentesis—right. Discharged. March 1, comes back because her right ear is discharging—started two weeks ago. Discharged April 7. Ears well, hearing about one-half normal in right ear.

CASE 16.—A. P., aged 16. December 15. Was slow in learning to talk. At times hears fairly well. When he takes cold, hearing is affected. To-day hears loud voice at 6 inches only. Sleeps with mouth open.

Examination.—Left drum-head scarred and retracted. Right external canal filled with pus. Right ear, loud voice, 6 inches; lef tear, cannot hear speaking voice. Tonsils and adenoids should be removed. Needs a meatomastoid operation.

Operation.—December 16, radical mastoid.

Bacteriology.—Colon bacillus.

Operation.—December 28, adenoids removed.

Result.—Complete recovery from operation; hearing in right ear about one-half normal.

CASE 17.—E. V., aged 15, January 7. Ear trouble began one week ago last Monday. Left ear began to ache, continued to ache for a couple of days, and then began to discharge. Has been discharging ever since and is painful most of the time. Mastoid region swollen after ear began to discharge. Had influenza and sore throat about one week before ear trouble began. Says she had ear-ache a great deal about eight years ago; does not remember which ear or whether it discharged any. Breathes through mouth day and night. When she catches cold has a dull pain over right antrum. Had ulcerated tooth on right side above one or two years ago. Nose constantly discharges—yellowish—no odor.

Physical Examination.—Right ear normal. Left ear, perforation of drum-head with discharge of pus. Drum-head bulging. Tenderness over mastoid. Pain in ear most of the time. High notes normal. Bone conduction better than air.

Diagnosis.—Left otorrhea and mastoiditis.

Operations.—January 7, paracentesis left ear-drum. January 13, left simple mastoid.

Pathology.—Mastoid cells small and all filled with pus: Not much necrosis. Exposed lateral sinus at knee.

Bacteriology.—Streptococci, some of them Gram-negative. *Micrococcus catarrhalis.* Hay bacillus.

Discharged February 15. Ears normal.

CASE 18.—M. G., aged 16. January 16. Has had trouble in right ear as long as she can remember. If she catches cold, she has ear-ache. Three or four years ago had ear-ache in right ear a great deal. One year ago, right ear discharged for two or three weeks. Discharge was purulent. Since then no discharge until middle of December, when she had measles. December 26, had a severe ear-ache; discharge began and has continued ever since, stopping at times for a day or two. Ear has been very painful; was swollen over mastoid region a part of the time. Ear and mastoid region have been massaged by an osteopath. Says she had tonsillitis several years ago, also on left side, when she had measles. Has had sore throat occasionally and could open her mouth only one-half inch.

Physical Examination.—Tenderness over mastoid. Pulsating ear-drum. Abscess under temporal muscle. High notes normal. Bone conduction better than air conduction.

Diagnosis.—Mastoiditis—right. Probably abscess under temporal muscle.

Operation.—January 20, right simple mastoid. Paracentesis right ear-drum.

Pathology.—Abscess in temporal muscle. Pus in mastoid antrum. Exposed lateral sinus. Badly necrosed bone extending to dura. Has pachymeningitis and perisinus abscess, with inflammation of walls of sinus. Dead bone lying next to brain and attached to dura. Bone between temporosphenoidal lobe and sinus all rotten. Granulations on lateral sinus. No evidence of leptomeningitis or local brain abscess. Dura not tense.

Bacteriology.—Staphylococci and Gram-negative streptococci.

February 10, sutured right mastoid. February 26, patient came back for examination; was to come twice a week for treatment. April 4, discharged—ear well.

May 11. Has come back for treatment of other ear. Hearing improved.

CASE 19.—L. R., aged 19. January 26. Right ear began aching January 25. Discharge began January 26; purulent and bloody. Soreness over mastoid; left ear aching some at present.

Operation.—February 23, simple mastoid, right. Results good.

Pathology.—All mastoid cells necrotic; dura not exposed.

Bacteriology.—*Streptococcus* and *Staphylococcus albus.*

Results.—May 13. Discharged, complete recovery.

CASE 20.—Mrs. L., aged 41. February 1. Sunday morning had an ear-ache. Right ear pains; has roaring in ears; hears water running, katydids, etc.

Examination.—Left drum-head retracted; pain on pressure over tip of right mastoid. Right ear, loud voice 4 feet; left, whisper 3 feet.

Diagnosis.—Right ear, abscess with mastoid involvement. Had ulcerated upper molar on right side. Just above second molar on right side is a discharging sinus. Has had discharge from nose before. Exploratory puncture of right antrum; lots of pus.

Diagnosis.—Empyema of antrum of Highmore secondary to necrotic tooth.

Operation.—February 3, right simple mastoid. Infected with gas-producing organism; gas bubbled up when antrum was approached and also when ear-drum was cut. Pain in antrum.

Bacteriology.—*Streptococci, Micrococcus aerogenes capsulatus* and *B. subtilis.*

Operation.—Right radical antrum, middle and third molars removed. With the third there came away a part of the alveolar process, which was necrotic, and left an opening into the antrum. Antrum was filled with polyps.

March 24, canal has been dry for several days.

May 2, mastoid and antrum well. Return for closure of opening between antrum and mouth. Result normal.

CASE 21.—M. G. March 3. Last Wednesday had a sore throat and right ear started to ache, is still aching. Has a sense of fullness in right side of head. Mastoid region very tender. Glands at angle of jaw very painful. Six weeks previously had appendicitis and was operated on. A few days later temperature rose to 105 F., and examination showed an abscess at site of operation. Bacteriologic examination of the pus showed streptococci. She recovered from this and was about to be discharged from the hospital when the ear trouble began.

Ear discharged when she was a very small child. Also discharged last year. Tonsils become inflamed whenever she catches cold. Are inflamed now. Cannot see very well; wears glasses. Has headache, photophobia; eyes water a great deal.

Left ear normal. Right ear, drum head bulging and a little red. Slight tenderness at mastoid tip. Bone conduction better than air conduction. High notes normal; whisper, 10 inches; speaking voice, 6 feet.

Operations.—March 3, paracentesis, right ear. March 10, right simple mastoid.

Pathology.—Necrosis of antrum; dura over middle fossa and lateral sinus exposed. Granulations over middle fossa on dura.

Bacteriology.—Gram-negative streptococci.

This case is particularly interesting from the fact that the ear infection followed so soon after the appendicular abscess and was caused by the same organism. The infection was evidently carried by the blood. Recovery complete.

In two of these cases the mastoid antrum was normal and pathogenic bacteria were found. In one other case not included in this series, I found pathogenic bacteria in the normal antrum.

There were thirteen chronic cases and six acute cases. In seven chronic cases, staphylococci were found. In only two cases were they the only organism found. In three of the chronic cases streptococci were present, but not in pure culture. In two chronic cases pneumobacilli were found in pure culture. Colon bacilli were found in two chronic cases, once in pure culture, once with *Bacillus diphtheriæ.*

Diphtheria bacilli occurred as a secondary infection in one acute case. In the six acute cases streptococci were found, three times in pure culture. In one acute case Gram-negative streptococci were the only germs found. Staphylococci were found in one acute case—not in pure culture. *Micrococcus aerogenes capsulatus, Micrococcus catarrhalis* and *B. subtilis* were found in mixed infections. In many cases no history was obtainable as to the cause of the disease. In two cases ear trouble followed scarlet fever; in one mumps and measles; in one influenza; in one tonsillitis; in one removal of adenoids; in one the disease followed empyema of the antrum of Highmore, secondary to a necrotic tooth. One was made worse by an attack of measles. Five cases were aggravated by taking cold. In most of the chronic cases and in one acute case, necrosis was extensive. It did not appear to be worse where streptococci were present.

SUMMARY AND CONCLUSIONS

1. Bacteria are normally present in the mastoid antrum. This is to be expected since there is a continuous passage from the throat through the Eustachian tube and middle ear to the antrum.
2. Mastoiditis is caused by a variety of organisms. Those found in my cases were *Staphylococcus, Streptococcus, Micrococcus catarrhalis,* diphtheria bacillus, *B. coli communis,* pneumobacillus, *B. aerogenes capsulatus, Micrococcus tetragenus,* sarcina, and *B. subtilis.*
3. In three cases of ear disease Gram-negative streptococci were found.
4. The few patients who were treated with vaccines after operation were remarkedly benefited.

I wish to thank Dr. Dean for the opportunity of studying these cases, also for the suggestions he has given me in my work, and for the use of his private library.

207 North Capitol Street.

New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED BY THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. THEIR ACCEPTANCE HAS BEEN BASED LARGELY ON EVIDENCE SUPPLIED BY THE MANUFACTURER OR HIS AGENT AND IN PART ON INVESTIGATION MADE BY OR UNDER THE DIRECTION OF THE COUNCIL. CRITICISMS AND CORRECTIONS ARE ASKED FOR TO AID IN THE REVISION OF THE MATTER BEFORE PUBLICATION IN THE BOOK "NEW AND NONOFFICIAL REMEDIES."

THE COUNCIL DESIRES PHYSICIANS TO UNDERSTAND THAT THE ACCEPTANCE OF AN ARTICLE DOES NOT NECESSARILY MEAN A RECOMMENDATION, BUT THAT, SO FAR AS KNOWN, IT COMPLIES WITH THE RULES ADOPTED BY THE COUNCIL.

W. A. PUCKNER, SECRETARY.

CALCIUM PHENOLSULPHONATE—Calcii phenolsulphonas—Calcium Sulphocarbolate.—Calcium 1,3-phenolsulphonate. $[C_6H_4(OH)SO_3]_2Ca = Ca(C_6H_5O_4S)_2$ is the neutral calcium salt of para-phenolsulphonic acid.

Calcium phenolsulphonate occurs as a white, or faintly pinkish-white, almost odorless powder, having an astringent, bitter taste. At high temperatures the salt chars, emits inflammable vapors having an odor of phenol, and finally leaves a residue of calcium sulphate.

The salt is easily soluble in water and in alcohol.

An aqueous solution of the salt (1-100) should assume a pale violet color on the addition of ferric chloride test solution.

If 5 Gm. of the salt be percolated with 25 Cc. of ether in a small filter, the solvent allowed to evaporate spontaneously and the residue, if any, dissolved in 5 Cc. of water, the solution should not give a white precipitate upon the addition of a few drops of bromine test solution (absence of *phenol*).

An aqueous solution of the salt (1-100) should not respond to the time-limit test for *heavy metals* prescribed by the United States Pharmacopeia, Eighth Revision.

An aqueous solution of the salt (1-100) acidified with a few drops of diluted hydrochloric acid should give no immediate turbidity after addition of 1 Cc. of barium chloride test solution (limit of *sulphate*).

If dried to constant weight at 100° C. (212° F.), the salt should not lose more than 2 per cent. of its weight (absence of an undue amount of *water*).

If from 0.5 to 1 Gm. of the salt be dried to constant weight at 100° C. (212° F.) and the dried substance be slowly ignited in an uncovered crucible (care being taken that the contents be freely exposed to the air) until the weight becomes constant, the residue should amount to not less than 35.0 per cent. nor more than 36.0 per cent. of the weight of the dried substance.

Actions and Uses.—Calcium phenolsulphonate has the actions and uses of other phenolsulphonates (sulphocarbolates). It is believed by some to be an intestinal antiseptic, but most pharmacologists regard the antiseptic powers of the phenolsulphonates as feeble.

It may be prescribed in diarrhea and in diseased conditions in which it is believed that there is an undue amount of intestinal putrefaction.

Dosage.—The average dose is 0.5 Gm. (8 grains).

Non-Proprietary Preparations:

Calcium Phenolsulphonate, M. C. W.
Manufactured by the Mallinckrodt Chemical Works, St. Louis.
Calcium phenolsulphonate, Abbott
Manufactured by the Abbott Alkaloidal Co., Chicago.

Therapeutics

PRESCRIPTION-WRITING

CHAPTER V.—DOSAGE

The dose of a drug should be based on the age, weight and individuality of the patient, and the necessity for a strong action of the drug.

The frequency of the dose is determined by the results obtained, by the length of time it takes the drug to be eliminated or cease its action, and the possibility of its causing a cumulative effect.

While age is an all-important element in the determination of the dose, the weight, unless in the obese, is the most important element, except in the case of narcotics given to children. Children have more central nervous system as compared to their weight than adults, and therefore are more profoundly affected by drugs which act on the brain, than are adults. In other words, a given dose of a narcotic, especially of the opium series, for an adult must be more reduced in size for a young child than any table of reduction computed by age or weight would determine.

The best simple rule of dosage by age is the following:

At 20 years, the adult dose.
At 10 years, ½ the age, ½ the dose.
At 5 years, ¼ the age, ¼ the dose.
At 2½ years, ⅛ the age, ⅛ the dose.
At 1 year, 1/12 the dose.

Children whose ages are between the ones here specified may readily be prescribed doses a little more or less than the dose determined by the age nearest theirs in the table.

The relation of size and weight to the dose is all-important. A large child of 2 years should certainly receive a larger dose than a weakly, small child of the same age. Also a small adult of 20 should receive less than a large muscular individual of the same age. The blood of an adult represents about one-thirteenth of his total weight. This is not true of children or of the obese. Hence the dose of an obese individual may be even less than if his weight were normal.

The following are the average weights for normal adult males. It should be remembered that females up to the age of 45 or 50 generally weigh less than males; also that a range of from 20 to 25 pounds above or below the average weight, the patient's general condition being good, is not necessarily considered a weight too high or too low for acceptance as an insurance risk. Above or below this range of 20 to 25 pounds from the average is generally considered over-weight and under-weight, and the acceptance of such an individual for insurance becomes questionable.

TABLE OF AVERAGE WEIGHT TO HEIGHT AT DIFFERENT AGES

	Year							
Ft. In.	15–24	25–29	30–34	35–39	40–44	45–49	50–54	55–60
5–0	120	125	128	131	133	134	134	134
5–1	122	126	129	131	134	136	136	136
5–2	124	128	131	133	136	138	138	138
5–3	127	131	134	136	139	141	141	141
5–4	131	135	138	140	143	144	145	145
5–5	134	138	141	143	146	147	149	149
5–6	138	142	145	147	150	151	153	153
5–7	142	147	150	152	155	156	158	158
5–8	146	151	154	157	160	161	163	163
5–9	150	155	159	162	165	166	167	168
5–10	154	159	164	167	170	171	172	173
5–11	159	164	169	173	175	177	177	178
6–0	165	170	175	179	180	183	182	183
6–1	170	177	181	185	186	189	188	189
6–2	176	184	188	192	194	196	194	194
6–3	181	190	195	200	203	204	201	198

In determining the dose it is most important to consider whether or not the patient has any exceptional susceptibility to the given drug. When an idiosyncrasy or abnormal susceptibility to a certain drug or to drugs of a certain class is known, the drugs causing it should, if possible, not be administered. That peculiar phenomenon, now known as anaphylaxis, is one which also should be taken into account in this connection.

Sometimes such undesired action of a drug occurs with the first dose only, notably in the case of quinin, and a tolerance to the drug is, after this first dose, temporarily acquired.

Another idiosyncrasy of a patient may represent a *tolerance* to a drug such that large doses must be given to produce any effect. This tolerance may be natural or acquired by previous use of the drug.

Still other very important predispositions of a patient are caused by the disease affecting him, by the condition of his digestive and absorptive system, and by the condition of his eliminative organs. The disease present may create a tolerance or an increased susceptibility to a drug. Slow absorptive powers may render the action of the drug almost impossible or allow accumulation of dangerous amounts of the drug (under which conditions the drug should be given hypodermatically, if it is needed). Slow or retarded elimination due to defective eliminative organs will allow cumulative action of many drugs.

The drugs which are most frequently found unexpectedly to cause undesirable or even serious symptoms in susceptible individuals are quinin, salicylates, atropin-containing drugs, iodin-containing drugs, and opium and its alkaloids.

The diseased conditions that most seriously modify (lessen) the dose of a drug are nephritis and cirrhosis of the liver.

A condition of shock precludes immediate absorption from the stomach, hence such a condition must be combated, if by drugs, hypodermatically.

Frequency of the Dose

It should be carefully learned how long, ordinarily, it takes a given dose of a drug to act, and how long before it is mostly eliminated. This determines the frequency of the dose. Also some drugs are eliminated so slowly that they tend to accumulate in the system or are deposited in the various organs so that medication may occur by autolytic action some days and even weeks after the cessation of the administration of the drug.

A few of the rapidly acting drugs are:

Alcohol
Ammonia
Camphor
Caffein
Chloral
Iodids
Salicylates
Strophanthin
Strychnin

These act in a few minutes to an hour or so, hence the intervals at which they may be given range from every hour to every three hours, or three times a day, according to the drug.

A few of the slowly acting drugs are:

Arsenic
Atropin
Bromids
Digitalis
Mercury
Quinin
Synthetic antipyretics
Synthetic hypnotics
Thyroid

These act in from several hours to twenty, hence should be given once or twice a day, according to the drug.

A few of the drugs that tend to accumulate in the system are:

Arsenic
Atropin
Bromids
Digitalis
Mercury
Strychnin

Many drugs cause eruption on the skin either due to irritation of the stomach and duodenum or to their being more or less excreted by the skin and irritating the glands during such excretion, or they may cause flushing of the skin.

Examples of drugs causing the first kind of irritation are: copaiba, chloral, opium, quinin, salicylates, synthetic compounds, volatile oils; drugs of the second type are arsenic, bromids and iodids: those of the third type are antitoxin, atropin and thyroid.

It should always be remembered that some drugs are excreted into the milk; hence if the mother is nursing her baby, some drugs should be avoided, and some given only infrequently; or on the other hand, the baby may be medicated through the mother.

Generally speaking most narcotics (opium, bromids, etc.); most so-called alteratives (arsenic, mercury, iodids, thyroid); most cathartics; and quinin are excreted by the milk.

CHAPTER VI.—METHODS OF ADMINISTERING DRUGS

Drugs and serums are more than occasionally administered intravenously, but as the technic requires skill, most perfect asepsis, and should require the enforcement of at least twenty-four hours of absolute rest, this method is not likely to be frequently resorted to. Moreover it seems to be a fact that, when a drug or serum is injected intramuscularly, the rate of absorption and activity of a substance is almost as rapid as when it is given intravenously, and the danger of accidents is much less.

The hypodermatic or subcutaneous method is of very great value in all emergencies, but should not be used too frequently. Of course the most frequent need for such medication is caused by pain, which must be combated by morphin or its equivalent, and the danger of acquiring a habit is greater when the drug is used hypodermatically than when it is given in any other way.

Of course the most frequent method of giving a drug is by the mouth, either in liquid, powder, pill, capsule or tablet. A drug will surely act more quickly if given in liquid solution, and more quickly on an empty stomach. If it is disagreeable, however, it should be given in capsule if the character and dose of the drug will allow it. Also if a drug is irritant, it should not be given on an empty stomach. A disagreeable liquid drug should not be combined with a syrup, which does nothing but prolong the taste and upset the stomach, but should be given in plain water to be followed by any kind of taste the patient prefers, such as orange, lemon, or by a peppermint or wintergreen candy for example. Or the liquid may be given in a sour mixture as lemonade or syrup of citric acid and water, or it may be given in a mineral or carbonated water. A powder may be given in milk or in an effervescing water.

Capsules are the nicest means of giving drugs disagreeable in taste and small in dose. The contents of a capsule should be dry for rapid solution, the principal advantage of a capsule over a pill. If rapid action is desired, or if it is feared that the capsule, slowly dissolving on a small part of the mucous membrane of the stomach will irritate the membrane, the capsule may be uncapped at the moment of swallowing, and the result is the same in the stomach as though the drug had been taken in powder. Alcohol in any form in the stomach will retard the solution of a capsule. Pills are not so much used as before the capsule became so popular. The solution and absorption of a pill must be slow, unless it contains some particles of a substance that swells with water, as starch. Sugar, chocolate, or gelatin-coated pills and tablets make the solution still slower, though in the case of drugs to act on the intestine this may be of advantage.

The much-used tablet, compressed or triturate, doubtless renders much medication valueless, and perhaps, fortunately, harmless. The speed of solution of most tablets on the market is problematical, hence if the action of a tablet is immediately desired it should be predissolved, or at least crushed by the teeth before swallowing. All antipyretic coal-tar tablets should be crushed before swallowing and then a good drink of water taken with them. It should not be forgotten that anything that may bite or irritate the membrane of the mouth will do the same to the mucous membrane of the stomach. Hence bromid tablets should never be taken undissolved. Potassium chlorate tablets dissolved in the mouth or swallowed are dangerous. Potassium chlorate solutions for the mouth and throat are valuable, but there is no justification for ever taking potassium chlorate into the stomach or into the system.

A very soluble tablet dissolved and absorbed from the mouth will give almost as rapid action as when given hypodermatically.

The rectum absorbs drugs given by means of suppositories or injections nearly and sometimes quite as rapidly as does the stomach. But sedatives and some laxatives only are ever administered by suppositories for systemic effect.

A few drugs are given endermically, but except in the case of mercury the method is uncertain.

Mucous membranes may be treated by douching, injection, insufflation, and those of the air passages by inhalation. Some drugs are absorbed by all of these methods, and if poisonous drugs are used, the possibility of too great an absorption must always be kept in remembrance.

THE ALLEGED HYGIENIC VALUE OF OZONE

We have already on several occasions discussed the use of ozone for the purification of drinking-water and have pointed out some of the reasons why under present conditions this is of limited application. There is no doubt that ozone is an effective sterilizing agent when added to water containing little organic matter, or that its use appeals to the popular prejudice in favor of a substance that leaves behind it no foreign chemical residue in the water treated. At present, however, the controlling factor in the installation of an ozonizing plant is its relative cost compared with other equally effective methods of water purification.

Attempts are now being made to extend the hygienic—and the commercial—uses of ozone still further. It must be admitted that in some directions at least these attempts are not justified by any evidence at hand. As a gaseous disinfectant of rooms and apartments ozone has never been widely employed, although a few experiments have seemed to indicate that it might be used for this purpose. It must be remembered that the ordinary method of production of ozone by electrical discharges at high tension rarely if ever yields a pure gas, but that the ozone is mixed with other gases, especially hydrogen peroxid and the oxids of nitrogen. Since these gases possess germicidal power and since the actual amount of ozone itself that is produced undoubtedly varies greatly with different machines and under different conditions and is not readily and accurately determinable, it is difficult to carry out conclusive experiments. Indeed, investigators generally recognize that some of the effects commonly attributed to ozone are due to the peroxids of nitrogen and hydrogen.

In view of this uncertainty regarding the more easily measurable effects of ozone it behooves us to look conservatively on the claims sometimes made for ozone as a substance which, inhaled in small quantities, is beneficial to health. The recorded evidence on which such a claim is based is extremely slender. Indeed, there is reason for believing that when the percentage of ozone in the air goes beyond a certain point, not only irritation of the respiratory tract is produced, but also other injurious effects. If the experiments of Schultz on chronic ozone poisoning are open to the objection that the effects observed were due to the nitrogen oxids mixed with the ozone rather than to the ozone itself, there is ground for reflection in the fact that such nitrogen compounds are always formed in greater or less abundance by the ordinary methods for producing ozone unless special care be taken to dry the air on which the ozonizer acts. In other words, untoward physiologic effects have been observed in animals treated with ozone and the mixture of gases with which ozone is practically always associated, and no physiologic benefit has been indubitably demonstrated.

Such facts justify hesitation in deciding on the installation of those forms of ozone-generating apparatus recommended for "purifying the air." There seems to be no doubt that disagreeable odors may be destroyed or neutralized by the gases formed by such machines, but one may be allowed to be skeptical as to the "sterilizing" of the air through their action. Certainly the benefits to health to be expected from the inhalation of varying and unknown quantities of ozone are purely conjectural. There is after all no more reason for accepting without investigation the statements of manufacturers about the hygienic properties of the machines they manufacture than for believing implicitly the assertions of nostrum-promoters.

THE PARATHYROIDS AND CALCIUM METABOLISM

It may be regarded as established beyond reasonable doubt that a relationship exists between tetany and removal of the parathyroid glands. MacCallum and Voegtlin[1] have suggested that this relationship may be due to the influence of the parathyroids on calcium metabolism. For they found that removal of the parathyroids was followed by increased calcium excretion with diminution of the calcium content of blood and brain, and that the tetany following extirpation of the glands could be avoided by the injection of calcium salts. This relationship between the parathyroids and calcium metabolism has recently received striking confirmation by Erdheim[2] and several co-workers, who have studied the effects of parathyroidectomy in white rats. In rodents the incisor teeth present the peculiarity of constant growth, resembling skeletal bone in this respect, so that they afford remarkable opportunities for the study of the details of calcium deposition. During a series of experiments on the relationship between parathyroid extirpation and tetany, Erdheim noticed that the incisor teeth of the rats became liable to repeated fracture, and a careful study of this phenomenon has led to several interesting observations. In the normal incisor tooth of the rat, the dentin forms the principal portion; a conical pulp cavity pierces this longitudinally, and a narrow zone of dentin adjoining this cavity is normally undergoing calcification, while the greater part has already received its complete deposit of calcium.

---

[1] MacCallum and Voegtlin: Jour. Exper. Med., 1909, xi, 118.

[2] Erdheim: Frankfurt. Ztsch. f. Path., 1911, vii, 178.

On removal of the parathyroids, it was found that calcification of the dentin at once ceased more or less completely; the portion already hardened underwent no change, but as the effects of use wore down this older part, the new uncalcified dentin taking its place lacked strength, and fractures followed. Imperfections in the enamel deposit also occurred, though at a later period than the alterations in the dentin. By regulating the time between extirpation of the glands and examination of the tooth, all transitional stages between the normal tooth and one almost completely decalcified could be obtained.

Still more interesting results followed the transplantation of the parathyroids. Owing to the great difficulty of getting successful growth of the transplanted organs in a second animal, the earlier work was limited to the transference of the glands from the neck to the abdominal wall. This was successfully accomplished in nine cases, and in each of these there was found in the incisor teeth a zone of uncalcified dentin, corresponding to the period of parathyroid quiescence, interposed between two layers of normal dentin. Transplantation of the gland from one animal to another in which the parathyroids had been previously extirpated was successful in only one instance. In this animal, some time before the examination of the teeth, the transplanted glands were also removed. Corresponding to the period of removal of the animal's own organs, there occurred a zone of uncalcified dentin. Another partially calcified zone indicated the period of activity of the transplanted glands, and a third zone, completely lacking in calcium salts, recorded that of the second removal.

In the face of such evidence, there can be little doubt of the influence of the parathyroids on calcium metabolism. Additional proof has been afforded in the case of skeletal bones by Erdheim and by Canal, who have both shown that under the influence of removal of the parathyroids callus formation is greatly retarded, owing almost entirely to deficient calcium deposition.

Erdheim does not hesitate to call attention to the similarity between his findings and those in rickets and osteomalacia. As additional links between the two processes he cites the relative frequency of hypertrophy of the parathyroids in osteomalacia, and the almost exact similarity in the changes of rachitic teeth and those of his animals. Although a connection between tetany and rickets has long been noted, it would as yet be premature to ascribe all cases of both unreservedly to lesions of the parathyroids. It has been found by Badt and Klose[3] that changes analogous to those of rickets and osteomalacia occur in young dogs after removal of the thymus, so that at present the pathologic basis of these diseases cannot be stated with any degree of certainty. However, it is possible that as complicated a process as the calcium metabolism of the body may be influenced by any one of several factors, and that the similar clinical findings may have various sources, as for instance is the case with experimental diabetes. Apparently, however, the problem of the etiology of rickets and osteomalacia is in a fair way toward being made clear, and its ultimate solution should merely be a matter of farther work along lines already indicated.

SANITARY DISPOSAL OF EXCRETA WITHOUT SEWERS

Farmers' Bulletin 463, entitled "The Sanitary Privy," recently issued by the Department of Agriculture, is of interest not only on account of its contents but also because it shows useful cooperation between two federal departments for the promotion of public health. The pamphlet was prepared by Drs. Stiles and Lumsden of the Public Health and Marine-Hospital Service, and embodies material previously published in bulletins of that service, reference to which has already been made in THE JOURNAL.[1] Fortunately it is now published and distributed by the Department of Agriculture. We say fortunately, because the latter arrangement secures a wider circulation, since Congress, we believe, has authorized the printing and reprinting of farmers' bulletins up to 1,000,000 copies, whereas it limits the publications of the Public Health and Marine-Hospital Service to one or two editions of 5,000 each.

Drs. Stiles and Lumsden for some years have been making a study of certain diseases which are particularly incident to farm life, and in a preliminary statement Secretary Wilson appeals to the American farmers to consider carefully the facts presented in this bulletin and to make practical use of the suggestions.

The authors discuss in popular language the diseases spread on the farm by soil pollution, emphasizing especially typhoid fever and hookworm disease, but also referring to dysentery and various other diseases of parasitic origin. There are, it is said, 2,000,000 cases of hookworm disease in the United States, all the result of soil pollution and mostly on the farm, and about 400,000 cases of typhoid annually, and most of the cases are due to the lack of proper disposal of human excreta. With the rapid improvement of sanitary conditions in the cities, typhoid is becoming more and more a disease of rural prevalence and origin, and in the country its spread results largely from the use of insanitary outhouses. Hence the disposal of excreta on the farm is one of the great sanitary problems, one that affects the whole nation, and the appearance of this practical bulletin is timely.

The authors discuss the shortcomings of the conveniences usually found on the farm and then describe three types of sanitary privies—those constructed on the "dry system," the "wet system," and the type developed at the Hygienic Laboratory in which use is made of the principle of the septic tank. The advantages and disadvantages of each are pointed out. The question of the ultimate disposal of the excreta is also discussed. The use of human excrement as fertilizer, except after its thorough disinfection, is unqualifiedly condemned; this practice is prohibited by law in some states. Reference is also made to the striking experiments of Stiles and Gardner[2] which show that fly larvæ in human excrement, buried six feet under sand, are able to make their way in large numbers to the surface.

---

[3] See editorial: The Function of the Thymus, THE JOURNAL A. M. A., March 25, 1911, p. 898.

[1] Discussion on the Sanitary Outhouse, THE JOURNAL A. M. A., Jan. 28, 1911, p. 255.

The practical character of the bulletin is shown by the fact that the authors have secured from a practical carpenter precise directions, with diagrams, for building a sanitary privy; they state that any 14-year-old schoolboy of average intelligence and mechanical ingenuity can, by following the directions, build such a privy at a total cost of five to ten dollars. Directions and estimates are also given for the building of sanitary outhouses for country schools and churches; they would be equally useful for country boarding-houses. Owners of the latter would do well to give these suggestions careful consideration, for already many city people are prevented from going to the country by the primitive sanitary arrangements existing there.

Some skepticism may be felt about the adoption by farmers of such suggestions as those contained in this bulletin; but when one considers how widely many other suggestions made to farmers (the building of improved barns, poultry houses, silos, the use of hog cholera serum, etc.), have been accepted although relatively expensive, there is reason to believe that these suggestions will before long be rather widely accepted by the intelligent element of rural communities. The physicians practicing in such communities can do much in this work, for people are in the most receptive mood for suggestions when they are suffering, or are threatened with suffering, as the result of the neglect of proper precautions. Such activity will also redound to the credit of the physician, for the public is judging members of the profession more and more by their attitude in respect to preventive medicine and their ability to protect the well from communicable diseases.

Physicians residing in a rural community, or having occasion to go there, will be interested in the perusal of this bulletin, which may be obtained by applying to the Department of Agriculture or to a congressman.

Variations in Male and Female.—The greater tendency of males to both physical and psychic variations from the normal, says Stewart (*Medical Record*), has been taken as an indication of their less stable character. Without enumerating the long list of well-known abnormalities and malformations, as clubfoot, harelip, cleft palate, supernumerary digits and nipples, common in both sexes, suffice it to say that, with the exception of congenital dislocation of the hip and a few other minor malformations, such variations are much more frequent in males than in females. The same rule holds good in regard to psychic variations. If geniuses, including musical and mathematical prodigies are more frequent among men, idiots and cranks are less frequent among women.

Current Comment

WHAT'S THE MATTER WITH KANSAS?

"Professor" Samuels of Wichita, Kansas, is a faker who claims to cure practically every disease in the calendar. He gets his victims through newspapers, and he evidently gets a great many, for he is able to carry full-page advertisements in the large metropolitan dailies, to say nothing of hundreds of smaller advertisements in less expensive newspapers. His "remedy" is an "eye-water." Analyzed by the chemists of the American Medical Association, it was found to consist essentially of a mixture of equal parts of salt and sugar in hydrant water. The price of the mixture is $25 an ounce. It does not take an expert to prove that such a mixture will not cure consumption, blindness, paralysis, Bright's disease or any of the hundred other ailments that Samuels professes to treat. Expert knowledge is not required to declare the treatment a fraud and the "Professor" a swindler. It is a conservative statement to say that a man who will take money from a consumptive, an epileptic or a victim of the morphin habit under the pretense of curing his disease with a mixture of sugar, salt and water is an unconscionable scoundrel. We believe that this man can be put out of business under the existing state laws in Kansas. If on no other grounds, he can at least be declared a swindler for obtaining money under false pretenses. Unless we are mistaken, this man tried to work the same scheme in Oklahoma, but the authorities there made life such a burden for him that he sought a more complaisant community. This he has apparently found at Wichita, Kansas. What's the matter with Kansas?

KEEP THE TOOTH-BRUSH CLEAN

Another time-honored and long-cherished institution has been attacked by the ruthless scientist and hygienist. This time it is the tooth-brush. Soap and the tooth-brush have hitherto been considered almost indispensable adjuncts of civilization. After years and years of patient teaching of the young that correct personal hygiene required the use of the tooth-brush, after its adoption as a necessary or desirable part of the accouterment of the United States soldier, who proudly carried it, stuck in the band of his hat, in the campaigns in Cuba, Porto Rico, the Philippines and in the Boxer Rebellion in China, where it was observed and commented on favorably by the observers of the sanitary departments of the armies of the world, it is now to be discredited because it is not conformable to modern hygiene and sanitation. The tooth-brush, according to Smale and Jones,[1] becomes septic after being used once, each bristle becoming an inoculating needle by which the person using it may become inoculated with the multitudinous germs which flourish on it, producing pyorrhea alveolaris, with such serious possible sequelæ as anemia, gastritis and arthritis. They propose as a solution of the difficulty that a new brush be used each time, or that the brush be boiled for five minutes after each using, or that it be kept in a 1 per cent. solution of trikresol or a 10 per cent. solution of formaldehyd. It is a bit disconcerting to think that we have been going along all these years teaching the correctness of the use of the tooth-brush only to find that instead of being an aid to good personal hygiene it has been an instrument for creating or perpetuating infections. How long will it be before that remaining bulwark of civilization—soap—is also attacked and the warning given that the unctuous substance that we smear over our faces and bodies daily is nothing more nor less than an emulsion of deadly bacteria, and that it is only because of our high degree of natural resistance that we have not succumbed? Seriously, however, the contention of Smale and Jones should not be ridiculed, nor, on the other hand, should this useful instrument be discarded lest a worse state follow. But the danger of auto-inoculation with bacteria from the mouth by the brush perhaps is not to be feared so much as its contamination by extraneous matter from lack of proper care in keeping. The methods of disinfection suggested by Smale and Jones, while ideal, are not practical, because they will not be carried out. An effective method, and better because practical and more simple, would be to wash the brush thoroughly *after using, rinse it in an antiseptic* solution (boracic, for example) and then keep it in a bottle corked with antiseptic cotton. The hygienic condition of the tooth-brush is certainly a matter worthy of attention.

---

EXPENSIVE SUGAR OR CHEAP SACCHARIN, WHICH?

We have already called attention to the fact that, based on the findings of the referee board, the government has declared the use of saccharin in foodstuffs illegal. This official decision, made in April of this year, was to go into effect July 1, 1911. Immediately the makers of saccharin brought pressure to bear at Washington to have the time extended in which the use of their product in foods would be legal. The appeal was granted and the sophisticators of foods—and others—were officially notified that they might continue to use saccharin in the place of sugar until Jan. 1, 1912. Now as the time of probation draws to a close, the saccharin-makers are again appealing to Washington. The summer of 1911 has been an exceptionally hard one on the sugar-refiners. As every one knows, the price of sugar has steadily risen and there is every indication that it will go still higher. Under such conditions, it is natural that those manufacturers of foodstuffs who are more concerned with personal profits than public health should see in the present shortage of the sugar-crop the chance of a lifetime to substitute saccharin for sugar. Evidently then the demand for saccharin is likely to be greater within the next few months than it has been for years. This fact has been taken into account in Europe by the calling of an international conference to prevent the illegal use of saccharin, reference to which has been made in THE JOURNAL.[1] Most European nations have long forbidden the use of saccharin in foodstuffs. Great Britain, while not forbidding its use, puts a prohibitive tax on the product so that in that country it is practically as cheap to use sugar as saccharin. It now remains to be seen whether the three secretaries—the Secretary of Agriculture, the Secretary of Commerce and Labor and the Secretary of the Treasury—will again extend the period of probation for the use of this drug.

THE VIABILITY OF HOOKWORM EGGS

Completing some experiments begun in 1910 by Stiles and Gardner, a partial report of which was given last year, Stiles and Miller now make a final report[1] in regard to the viability of hookworm eggs. One object of the experiments undertaken was to ascertain how long the eggs would remain viable under methods of treatment similar to those present in connection with the barrel privy devised by Stiles for use in country districts. Stiles and Miller summarize their findings as follows: In fecal material kept in water in the examinations made after 68, 117, 144, 317, 323, 349, 357 and 358 days, all the hookworm eggs identified were dead. The longest period after which they found eggs alive under the conditions described was seventy days. They conclude that it seems fairly well established that fermentation for four months in the privy devised by them kills all the hookworm eggs, and that fermentation for three months will kill nearly all of them. This shows that the hookworm eggs are most tenacious of life. They survive probably for a longer time in the earth. Efforts to eradicate all possibility of infection in the highly polluted soil of some of the southern communities will, therefore, be a long, difficult task.

BOGUS SCIENTIFIC INSTITUTIONS

To a certain type of men the sign is of more importance than the thing signified. Europeans have long ridiculed what they are pleased to call the American weakness for bizarre and pseudo-scientific degrees, although, as a matter of fact, this foible is less an American than a European characteristic. In the Berlin Letter of this week,[2] reference is made to a fake scientific organization called the "Italian Physio-Chemical Academy" (Accademia fisico-chemica Italiana) of Palermo, Italy. This concern, which has been previously exposed in these pages,[3] issues "medals" and "certificates of membership" to such individuals as are willing to pay what these questionable honors cost. This Italian degree factory is not the only institution of its kind in Europe. In England, there is the notorious "Society of Science, Letters and Art of London,"[4] which for the mere nominal sum of one guinea ($5) will furnish an ornate "diploma" in sonorous Latin to those who are desirous of writing the magic letters "F. S. Sc." after their names. The "College of St. Columba," another English degree emporium, dispenses the titles "A. Ph." and "F. Ph." with the privilege of permitting the recipient to wear a hood of scarlet cloth lined with green velvet—all for 63 shillings ($16). Coming nearer home, most readers of THE JOURNAL remember the notorious "St. Luke's Hospital,"[4] which, from Niles, Michigan, issued "certificates of merit" at $20—when it was unable to get $25. After the demise of St. Luke's, it was resurrected as the "Christian Hospital"[5] in Chicago. This, too, after a brief period of activity, received its quietus. Presumably so long as there are individuals whose vanity can be gratified by the possession of a "diploma" or "certificate of membership" whose value is measurable only in dollars and cents, so long—provided the government does not interfere—will degree factories and diploma mills flourish; so long as there are shallow egotists to pour dollars into the hopper, so long will degrees and diplomas be ground out.

ANOTHER INTERFERENCE WITH THE FREEDOM OF CATTLE

This dispatch from Jackson, Miss., appears in a recent issue of the Natchez *News*, regarding the efforts being made in Yazoo County to suppress the cattle-tick:

> "The quarantine placed on cattle from Yazoo County appeared to have little effect until the stockmen of that county awakened to the realization that their stock would not be admitted to the Mississippi State Fair, at Jackson, during the latter part of the month. The embargo stung the farmers and they decided to take some drastic measure to eradicate the dreaded tick."

The *News* then gives the proceedings at a meeting of the city council, where strenuous measures were urged to wipe out this blot on the fair name of Yazoo County, and to permit her cattle to appear at the state fair. This is right, nor would any one object to any measures which the Jackson City Council might adopt, to rid the cattle of disease. But, incidentally, how many human beings are there in Yazoo County, Mississippi, to-day who are suffering from tuberculosis and typhoid fever, for example? Nobody knows! Will there be any quarantine against the people of Yazoo County on that account? Oh, no, they can all go to the fair and if any of them are suffering from these diseases, they can communicate the infection to others without hindrance. If one cow died of foot-and-mouth disease in Yazoo County to-morrow the fact would be known in Washington in twenty-four hours, and live stock inspectors would immediately invade Yazoo County. How many women and children died in that county last year? Nobody knows! They are only human beings, not live stock, and in a majority of the states in the union and in all of the southern states, the state pays no attention to the birth or death of a human being. A blooded calf or a pedigreed colt has its birth carefully registered, but the birth of a child is not worth recording. And when it comes to dying, if you are a human being, you can die whenever you like. The state has no money to waste in such "scientific nonsense" as finding out how many of its citizens have died during the past year, or whether the death-rate in Mississippi is growing or decreasing, or what diseases are killing its people. But ticks in cattle—that is a different matter. The cows must not be kept away from the state fair.

Medical News

ALABAMA

Fresh-Air Camp Open.—The Montgomery Antituberculosis League formally opened its fresh-air camp, September 11. The camp is 10 acres in extent, located on a piney hill, and has in addition to a central dining room and kitchen, seven cabins already furnished. The secretary of the league appeals for funds for the maintenance of the camp.

Condemns County Jail.—Dr. William H. Oates, Mobile, state prison inspector, reports that the Madison County jail at Huntsville is more insanitary and less fit for habitation that any other jail he inspected. He has therefore ordered the sheriff to remove all the prisoners from the jail to the Marshall County jail at Guntersville, so that the Madison County jail may be renovated and made habitable.

CALIFORNIA

Insists on Vaccination.—The school board of Fresno has issued an ultimatum that all school children who have not been vaccinated, shall be barred from the Fresno public schools.

Personal.—Dr. John T. Culver, Oak Park, was thrown from his automobile in San Francisco, October 5, and sustained painful injuries.——Dr. Josea O. Perrone, San Francisco, fractured his right leg and suffered internal injuries in a runaway accident near his summer home in Montebello.——Dr. Edwin D. Ward has been appointed assistant health commissioner of Los Angeles, vice Dr. Irving R. Bancroft, resigned.

Many Committed to Asylums.—During August the greatest number on record of commitments to the State Insane Hospital was made. In March, 1910, the month of next highest record, 180 commitments were made, while in August 263 individuals were sent to the state hospital. The number of liquor and drug addicts committed during August was eighty-three, an increase of forty-nine over the figures for the previous month.

Tuberculosis Research Board.—The investigation of tuberculosis conditions in the state for which an appropriation of $5,000 was made by the last legislature, was initiated by the State Board of Health, September 2, when an executive board to have immediate charge of the work was named, consisting of the five following members: Dr. George H. Kress, Los Angeles, president of the State Tuberculosis Association; Charles C. Browning, Los Angeles; Mr. A. Bonnheim of the White Crusaders of Sacramento; Dr. Richard G. Brodrick, executive secretary of the San Francisco Tuberculosis Association, and Miss Katherine Felton, formerly secretary of the Associated Charities of San Francisco.

CONNECTICUT

Appropriation for Epileptic Colony.—The governor-general has signed a bill passed by the general assembly appropriating $147,550 for the construction of buildings, sewage system, water-supply system, power-house, etc., for the State Colony for Epileptics, Mansfield.

GEORGIA

Free Typhoid Vaccination.—Dr. J. Payson Kennedy, health officer of Atlanta, announces that he is prepared to administer antityphoid vaccine free of charge to any one who desires.

Personal.—Dr. Lewis M. Gaines, Atlanta, has been elected professor of neurology in the Atlanta School of Medicine and appointed neurologist to the Tabernacle Infirmary.——Drs. John Funkle and E. C. Thrash have been elected assistant pathologists at the Grady Hospital, Atlanta.

New Clinics Opened.—Under the direction of the faculty of the Medical College of Georgia, Augusta, the south side clinic was opened in that city at Twelfth and Mauge streets. The clinic is in charge of Dr. William C. Lyle and will be principally for the use of colored people.——The Morris Hirsch Memorial Free Medical Clinic, Atlanta, was opened October 4, in the Jewish Educational Alliance Building. The clinic is strictly non-sectarian.

Sanatorium News.—At the September meeting of the trustees of the State Tuberculosis Sanatorium, Alto, Captain W. G. Raoul resigned as chariman of the executive committee and was succeeded by Dr. Jeff Davis, Toccoa. Dr. Henry R. Slack, La Grange, was elected vice-chairman. The board decided that as the legislature had reduced the appropriation for maintenance, a charge of $3.50 per week for 75 per cent. of the inmates would be made, beginning October 1; the balance of the inmates will be treated free of charge. The sanatorium has seventy beds, all of which are occupied.

ILLINOIS

Sues for Hospital Permit.—Mandamus proceedings to compel the Oak Park Board of Trustees to issue a license for the construction of a hospital in that village, were filed October 2 by counsel representing the West Suburban Hospital Association.

Personal.—Dr. and Mrs. Benjamin Gleeson and family, Danville, and Dr. Abner G. Downer, Princeton, have returned from Europe.——Dr. Albert E. Campbell, Clinton, has been appointed assistant to the chief surgeon of the Illinois Central System.

Hospital for Lake Forest.—Lake Forest is to let the contract for a contagious disease hospital which is to be one story in height, made of brick, with four wards, two wings, and a detached cottage for the caretaker. The building is to be erected on 3 acres of ground donated by the city.

Charities Conference.—The sixteenth annual State Conference of Charities and Correction will be held in Champaign, October 21-24, under the presidency of Sherman C. Kingsley, Chicago. On Sunday morning the pulpits of Champaign and Urbana will be filled by delegates to the conference. On Monday the Section on Children will meet. The afternoon will be devoted to the needy family, and in the evening a mass meeting of the Section on Correction and of the State Association of Poor-Farm Superintendents will be held. On Tuesday there will be a general meeting presided over by Dr. Frank Billings, Chicago, in which the present condition of charity and correction in the state will be discussed. The afternoon will be devoted to the discussion of the feebleminded and epileptics.

Chicago

Personal.—Dr. Frederick K. Ream has been appointed a member of the staff of the ear, nose and throat department of the Illinois Post-Graduate Medical School.——Dr. John B. Eaton has returned from Europe.

La Rabida Closes.—The fifteenth year of the work of the Jackson Park Sanitarium has closed. During the season more than 2,500 children were cared for in the sanitarium, nearly 2,000 of whom were ill enough to be placed on the hospital records. Nearly 1,000 mothers were cared for on their visits to the sanitarium during the season.

INDIANA

Hospital for Princeton.—It is reported that the city of Princeton will purchase for $15,000 the Princeton sanatorium, which cost $35,000, and will maintain the institution as a city hospital. This movement has the support of the local members of the profession.

Personal.—Drs. John W. Sluss, John A. Pfaff and Charles L. Cabalzer, Indianapolis, while busy in the operating room of the Deaconess Hospital, October 5, were robbed of their money and jewelry.——Dr. John K. Kingsbury has been appointed assistant bacteriologist to the Indiana State Board of Health.——A banquet was given by the Lake County Medical Society, October 12, in honor of Dr. William F. Howat, Hammond, recently elected president of the Indiana State Medical Association.——Dr. Samuel C. Thomas, Milroy, was severely injured by being run down by a horse recently.——Dr. Asa W. Brown, health officer of Bluffton, has resigned.——Dr. Sherman B. Hitt, Greensburg, has succeeded Dr. Curtis Bland as secretary of Greensburg Board of Health.

KANSAS

Home for Kansas Leper.—It is announced that Mrs. Mike Quint of Ellis County, a Russian, who is afflicted with leprosy, is to be isolated on a farm which will be given her by the state.

Endorses Health Board.—The Shawnee County Medical Society at its meeting October 3, passed resolutions commending the action of the State Board of Health and the health commissioner of Topeka for their admirable work in controlling the epidemic of small-pox in the city, and urging the strict enforcement of compulsory vaccination in the public schools.

MARYLAND

State to Use Typhoid Vaccine.—The State Board of Health has decided on the use of typhoid vaccine in all state institutions.

Monument Unveiled.—At the ceremonies connected with the placing of a stone marker over the grave of Assistant Surgeon Richard Waters, near Washington Grove, Montgomery County, October 11, ex-Governor Edwin Warfield delivered the address before about 1,000 persons. An original poem was read and the monument unveiled by descendants. The ceremonies were in charge of Daughters of the American Revolution and are the first of the kind in the state. A detail of the Maryland National Guard fired a salute.

Baltimore

Personal.—Dr. Max Kunstler has opened a small hospital on the second floor of his residence, where those who need it may receive attention free of charge.——Dr. George H. Everhart sailed for Europe, October 4.

Deaths by Accident.—Nineteen persons died from accidents in September and 323 met with accidents which were not fatal. Among the 342 accidents, nine concerned automobiles; two, horses; ninety-six, street cars; nine, steam cars; while twenty-nine persons were bitten by dogs.

Bazaar for Physicians' Widows' and Orphans' Home.—The ladies in charge of the Home for Widows and Orphans of Physicians will hold a bazaar at 1112 Madison Avenue, November 1-3. Luncheon and supper will be served on each day. Dr. Eugene F. Cordell is treasurer of the home.

Emergency Hospital Planned.—Movement is on foot for the establishment of an emergency hospital in that part of Baltimore bordering on the Patapsco River, and known as Highlandtown and Canton. Dr. William E. McClanahan, health officer of Highlandtown, and Drs. David W. Jones and Michael J. McAvoy, Canton, are in charge of the project.

Personal.—Dr. Howard A. Kelly returned to Baltimore October 9 in good health after his operation.——Dr. Nathaniel G. Keirle, director of the Pasteur Institute and city postmortem physician, was 80 years old October 10.——Dr. Henry T. Reynolds' buggy was demolished by a street car. He escaped with cuts and contusions and a severe shock.——Dr. Thomas J. O'Donnell, police surgeon, suffered the loss of his motor-yacht *Loyola*. It was totally destroyed at the wharf by fire, caused by back-firing, with a loss of $2,500.

Lectures to School Children.—Mr. H. Wirt Steele, executive secretary of the Maryland Association for the Prevention of Tuberculosis, delivered the first lecture and demonstration of the disease, October 10, before the children of the public schools. He explained the manner in which the disease is contracted and dwelt on the agency of public drinking-cups, dust, filth, bad ventilation, etc. The lecture was illustrated and the bacilli were shown under the microscope. The lectures will be continued daily until all the children have been reached.

MICHIGAN

To Study Occupational Conditions.—With the especial approval of Governor Osborn, the State Board of Health has authorized the secretary to bring about an investigation of the occupational conditions in Michigan, with a view to prevention of unnecessary loss of life and health from conditions that can be remedied. This work is to have the immediate attention of the department, a thorough investigation to be made of all industrial conditions that affect health and life.

Eugenics.—The State Board of Health at its meeting at Lansing, October 13, decided to employ Miss Adele McKinnie, an expert investigator in eugenics from the Eugenics Record Office, Cold Springs Harbor, Long Island, N. Y., as a special medical inspector, to investigate during the next six months the condition and extent of feeble-mindedness and mental deficiency in Michigan. Miss McKinnie's work will begin at the State Home for the Feeble-Minded and Epileptic, at Lapeer, under the immediate direction of Dr. George S. Chamberlain, medical superintendent of that institution.

MINNESOTA

Leper Dead.—After having suffered from leprosy for twelve months, Ludwig C. Dyregrow, a tailor, died September 25, at his home in Minneapolis.

Sanatorium Almost Ready.—The contractors report that the St. Louis County Tuberculosis Sanatorium, Midway, will be ready to receive patients, December 1.

"Tag Day" in St. Paul.—The women in St. Paul in their annual "tag day," October 11, collected more than $15,000, which will be used in the campaign against tuberculosis.——The St. Paul Antituberculosis Society has moved into new headquarters at the New York Life Building, Fifth and Minnesota Streets.

Dr. Wiley Upheld.—The Hennepin Medical Society at its last meeting adopted resolutions upholding Dr. Harvey W. Wiley and expressing satisfaction at the decision of the President in the case. The Northwestern Branch of the American Pharmaceutical Society also passed resolutions expressing confidence in Dr. Wiley.

NEVADA

State Society Meeting.—The eighth annual meeting of the Nevada State Medical Association was held in Reno, October 10-12. At the election, October 12, Dr. Benjamin F. Cunningham was elected president; Dr. Donald MacLean, vice-president, and Dr. Martin A. Robinson was reelected secretary and treasurer, all of Reno. The next meeting of the association will be held in Reno.

NEW YORK

Benefit for Crippled Children.—The annual benefit for Robin's Nest, a home for crippled children, at Tarrytown, netted $1.000.

State Charities Aid Association and Tuberculosis.—This organization has been sending copies of a set of resolutions to the various medical organizations which they believe will further their work in combating tuberculosis. Their slogan is "No Uncared-For Tuberculosis in New York State in 1915."

Cancer and Typhoid Show High Mortality.—The *Monthly Bulletin of the State Department of Health* states that cancer and other malignant tumors have destroyed nearly as many lives as tuberculosis; during July 1,064 deaths were charged to this cause. Deaths from epidemic diseases have been exceptionally few. The only disease that appears to be on the increase is typhoid fever.

New York City

Change of Name and Meeting-Place.—The New York Physicians' Association (formerly the East Side Physicians' Association) will hereafter hold its meetings at Tuxedo Hall, Madison Avenue and Fifty-Ninth Street.

Personal.—Dr. Thomas H. Curtin, coroner's physician, has returned from Europe.——Dr. and Mrs. Canfield, Dr. and Mrs. N. E. Brill and Dr. Charles Langdon Gibson have returned from Europe.——Prof. Silvio Tonnini of the University of Bologna arrived in New York, October 5.

Round Up Bad Food Sellers.—The board of health has been showing up the purveyors of bad eggs, meat and milk. In the court of special sessions, October 8, sixty men were arraigned accused of selling unwholesome or adulterated foodstuffs. The fines ranged from $10 to $500.

To Study Pellagra.—The department of tropical medicine of the New York Post-Graduate Medical School is planning to investigate pellagra in southern states in the spring. This is made possible by the gift for this purpose of $15,000 by Col. Robert M. Thompson and Mr. J. H. McFadden.

Lectures on Skin Diseases.—Dr. L. Duncan Bulkley will give the thirteenth series of Clinical Lectures on Diseases of the Skin in the out-patient hall of the New York Skin and Cancer Hospital on Wednesday afternoons, from November 1 to December 20 at 4:15 o'clock. The course will be free to the medical profession.

Plans for a New Hospital Filed.—The New York Society for the Ruptured and Crippled has filed plans for a new building which will be located on East Forty-Second Street extending from 303 to 325 and through to Forty-Third Street. The old building of the society was sold to the New York Central Railroad. The new building will be of brick and terra cotta and will cost $800,000.

City Death-Rate Again Breaks Record.—The Department of Health announces that the death-rate for this city for the week ended October 7 was the lowest recorded in the statistics of the state. The rate was 12.60 per 1,000, while for the corresponding week of 1910 it was 14.48. The low mortality is due to the decreased number of deaths at all the different ages grouped and is not confined to any one particular period of life. The city was freer from infection than at any time in its history, there being not one death from scarlet fever or measles reported.

NORTH CAROLINA

Personal.—Dr. Houston B. Hiatt, Ashboro, has been appointed local surgeon for the Southern Railway.——Dr. W. H. Hardison, Creswell, is reported to be critically ill in St. Vincent's Hospital, Norfolk, Va., after an operation for appendicitis.——Dr. Charles L. Minor, Asheville, has returned after a summer in the north woods of Canada.——Dr. Joseph Hyde Pratt, Chapel Hill, has been elected president and treasurer of the Southern Appalachian Good Roads Association, and Drs. Archibald Cheatham, Durham, and Chase P. Ambler, Asheville, have been elected members of the executive committee.

OHIO

Fraternity Incorporated.—The Alpha Xi Chapter of the Alpha Kappa Kappa of the medical fraternity has been incorporated in Cleveland.

Club Election.—At the annual meeting of the Celsus Club, held in Akron, September 28, the following officers were elected: president, Dr. Judson A. Hulse; vice-president, Dr. Samuel St. John Wright; secretary and treasurer, Dr. Edmund A. Weeks.

Personal.—Dr. William H. Stover, Tiffin, announces that he is about to retire from active practice.——Dr. William C. Leeper, McConnelsville, has leased property on Kennebec Hill on which he will build a number of cottages to be used as a sanatorium.

Northwestern Physicians Elected.—At the annual meeting of the Northwestern Ohio Medical Society, held in Marion, September 14 and 15, Lima was selected as the next place of meeting, and the following officers were elected: president, Dr. Martin Stamm, Fremont; vice-president, Dr. William A. Belt, Kenton.

PENNSYLVANIA

Diphtheria in Lebanon.—Because of thirty-three cases of diphtheria in Lebanon and more in the suburbs, the local board of health on October 14 closed all theaters and other public meeting places and no services were held in the churches.

Relief Fund for Austin Physicians.—A circular letter received at this office October 16 announces that the secretary of the Medical Society of the State of Pennsylvania, Dr. C. L. Stevens, of Athens, Pa., is authorized to receive the contributions for the relief of physicians who suffered loss by the flood at Austin. Disbursements will be made by the Committee on Benevolence of the society.

Philadelphia

County Society to Entertain Surgeons.—There will be a joint meeting of the Congress of Clinical Surgeons of North America and the Philadelphia County Medical Society, November 8. Following the scientific program the society will give a reception to the visiting members of the congress.

Plea for Special Courses in Sexual Hygiene.—Dr. Joseph S. Neff, director of public health and charities, in his weekly bulletin, made a strong plea for the introduction in the public schools of special courses in hygiene, to instruct children in the facts of life and their sex responsibilities. "Penitentiaries, insane asylums, institutions for the blind and homes for the feeble-minded would not contain 25 per cent. of their population had the present adult generation been properly instructed in their youth in social hygiene."

Municipal Research Bureau Recalls Director.—Dr. Jesse D. Burks will return to this city as the director of the bureau of municipal research. He was released three months ago at the request of the New York Board of Estimate to serve on a commission which is conducting a comprehensive inquiry into the public school system of New York. The bureau of municipal research has given active cooperation in several divisions of the bureau of health, where notable results have been obtained in the reorganization of the work in medical inspection, in milk inspection, child hygiene and the municipal hospital.

Banquets.—A reception and dinner was tendered by the Medical Club of Philadelphia, October 6, to the following newly-elected members of the medical faculty of the University of Pennsylvania: Drs. Gwilym G. Davis, orthopedic surgery; John B. Deaver, practical surgery; M. Howard Fussell, applied therapeutics; Milton B. Hartzell, dermatology; Edward Marlin, surgery; A. M. Pearce, research medicine; A. H. Richards, pharmacology; Alfred Stengel, medicine, and Alonzo E. Taylor, physiologic chemistry.——A banquet was given at the University Club, October 5, by Drs. J. Chalmers Da Costa and Edward Spitzka, in honor of Edward Croker, formerly chief of the New York Fire Department, and Dr. Harry M. Archer, honorary surgeon of the department.

Personal.—Dr. Harvey W. Wiley was one of the speakers at the Succoth Pilgrimage and fourteenth annual meeting of the National Farm School on October 15. Dr. Wiley was the guest of honor at a reception, arranged by the gentlemen's and ladies' boards of the farm school at Dr. Joseph Krauskopf's home in Germantown, October 14.——Dr. W. W. Cadbury, one of the five University of Pennsylvania men who are teaching in the Christian College at Canton, China, arrived in Philadelphia. October 13.——Dr. Herbert Fox has been appointed director of the Pepper Laboratory of Clinical Medicine.——Dr. William T. Porter, professor of comparative physiology in Harvard University, will deliver the fourth of the Weir Mitchell lectures of the College of Physicians, in Mitchell Hall. November 3, on "Shock."

Final Report of Pier Hospitals.—The reports of work done at the Race Street and Chestnut Street piers have been received by Dr. Joseph S. Neff, director of public health and charities and show that the Race Street pier cost $2.500 to maintain and the Chestnut Street Recreation Pier. $1,114.70; that a total of 340 sick babies were treated at the Race Street Pier. of which 241 were discharged, as cured, 30 as improved. 18 as unimproved, 8 transferred to other institutions and 43 died. The Chestnut Street Pier handled the whole question of infant hygiene, together with the instruction of mothers. A total of 10,743 infants were cared for there and 6.745 mothers and care-takers were instructed. Of all the infants. 2,862 were sick and 128 were sent to the Race Street Hospital. A total of 5.666 older children were cared for at Chestnut Street and 80 emergency cases were treated.

VIRGINIA

Personal.—Dr. Elliott T. Brady, Abingdon, has resigned from the State Board of Medical Examiners.——Dr. Aelpfar A. Marsteller. Thoroughfare, has been commissioned captain in the Medical Corps. Virginia Volunteers.

Tablet to Confederate Surgeon General.—At the meeting of the Confederate Memorial Library Society at Richmond. September 29. it was decided to install a tablet in the building on the site of the wartime residence of Brigadier General S. P. Moore, surgeon-general of the Confederate Army.

Academy of Medicine Election.—At the annual meeting of the Roanoke Academy of Medicine, October 2, the following officers were elected: president, Dr. E. Pendleton Tompkins, Roanoke: vice-presidents, Drs. Thomas D. Armistead, Roanoke, and Robert H. Garthright, Vinton; secretary, Dr. Lewis G. Richards. Roanoke. and treasurer, John W. Preston, Roanoke.

Free Treatment at Hookworm Dispensaries.—Free dispensaries, in localities where hookworm exists, are to be established by the State Health Department, which has charge of the contributions of the Rockefeller Commission in the state. Six points in Lunenburg County will be the first and other counties will be organized as rapidly as possible.

WEST VIRGINIA

State Association Election.—At the forty-fourth annual meeting of the West Virginia State Medical Association. held in White Sulphur Springs, September 20-22, Dr. Charles O. Henry. Fairmont. was elected president. and Dr. Arthur P. Butt. Davis. was reelected secretary. The next meeting will be held in July. 1912. at Webster Springs.

County Association Meeting.—At the annual meeting of the Ohio County Medical Association, held in Wheeling. September 18, the following officers were elected: president, Dr. Samuel L. Jepson: vice-president. Dr. Sylvanus S. L. Spragg; secretary. Dr. Earl F. Glass; treasurer, Dr. Reed McC. Baird; censors. Drs. Gustavus A. Aschman, N. Atwood Haning. and Harry M. Hall: delegates to the state association, Drs. Frank L. Hupp. William A. Quimby and John T. Thornton. and alternates, Drs. Samuel L. Jepson, Jacob Schwinn and E. A. Hildreth. all of Wheeling.

GENERAL

Bequests.—The following bequests to hospitals have recently been noted:

Catherine Deveney, Philadelphia. $15,000 to the Episcopal Hospital.

Mrs. Helen Hartley Lewis, New York, $125,000 to the new Polyclinic Hospital.

William A. Lawrence. Goshen, N. Y.. $5,000 to the Seney Hospital. Brooklyn.

Mrs. Caroline C. Thompson, Bridgeport. Conn.. $5,000 for a free bed in the Bridgeport Hospital for colored residents.

Oto-Ophthalmologists Organized.—The Pacific Coast Oto-Ophthalmological Society has been organized in San Francisco, with an initial membership of forty and the following officers have been elected: president. Dr. John F. Dickson. Portland, Ore.: vice-president. Dr. William H. Roberts. Pasadena. Cal.; secretary and treasurer. Dr. Cullen F. Welty. San Francisco; the executive committee. Drs. William A. Martin. San Francisco. Henry La Motte, Seattle, Wash., and John F. Dickson, Portland. Ore.

Milk Standards Commission Meeting.—**The Milk Standards** Commission of New York. of which Dr. William A. Evans, Chicago, is chairman, and Dr. Charles E. North, New York City. secretary, its membership being made up of health officers. bacteriologists. veterinarians and others interested in and connected with the milk industry, met in New York City, October 5 and 6. The commission recommended the adoption of four grades of milk: (a) certified milk, or its equivalent; the standards being those of the American Association of Certified Milk Commissions and of the Laboratory Section of the American Public Health Association; (b) inspected milk from tuberculin-tested cows from dairies scoring over 70 on the government score-card. temperature 50 F. and below. and bacteriologic count less than 100.000; (c) pasteurized milk with a bacterial count of less than 50,000. and a temperature of 50 F. or below: (d) cooking milk from dairies scoring 40 or less on the government's score-card. with a bacterial count of over 1,000,000; pasteurization required. The commission also recommended that the dirt test, bacteriologic standards, obligatory dating. prohibition of the sale of old milk. and a requirement of a temperature of below 50 F. be made a part of all municipal ordinances. It recommended further that the quality of milk as regards butter fat should be on one of two bases: that cities shall have an ordinance requiring a certain percentage of butter fat, or that dealers shall guarantee a certain percentage of butter fat. and shall be held responsible for the amount thus guaranteed.

FOREIGN

Eugenics at Constantinople.—The cable states that the head of the Armenian church at Constantinople has decreed that henceforth every couple applying to be married by the Armenian church must present a certificate from a qualified physician stating that both are in perfect health.

Epidemic Poliomyelitis in the Scandinavian Countries.—A Danish exchange says that there is no doubt that poliomyelitis is assuming an epidemic character in Sweden and also in Denmark. Other advices report about forty-six cases this year at Christiania. with eleven deaths, with a total for Norway of 743 cases and seventy-six deaths, the disease being more prevalent in the rural districts. The epidemic is said to show the peculiar features of former epidemics, especially the way in which only one person within the same household has been attacked. and even within the same building the cases have appeared as isolated; no connection between the cases could be detected. Several of the patients in Christiania were found to have been in the country immediately before the onset of the disease. Flies have been mentioned as disease-carriers; also chickens. The only preventive measure so far has been segregation. The schools have been closed in certain rural districts where the disease has been markedly prevalent; in the cities this measure has not been carried out. only those children who came from households of which a member has been attacked have been kept from school for seven days. In one town the authorities exclude children from school if there is a case of poliomyelitis in the building where they reside, even when not in their own family. Up to September 12 only three adults had been attacked by the disease. and in a more severe form. The health authorities have advised the population to be on the watch for passing paresis. catarrhs, stomach irregularities and brief febrile illnesses as possibly abortive forms of the disease.

CANADA

McGill Opens.—McGill University, Montreal. has a large increase in attendance. Freshmen in the medical department number seventy-one. the largest medical freshman class in six years.

New Hospital.—It is planned to establish a hospital at Yarmouth. N. S., as the only one in that city is its small Seamen's Hospital which is inadequate to the needs of the community.

Tuberculosis Supervision.—Toronto is now caring for 418 cases of tuberculosis under the supervision of municipal nurses. Of this number 117 are in sanitariums.——About 100 cities and towns in Canada are now engaged in the war against tuberculosis.

Opening Academy Meeting.—The Academy of Medicine, Toronto. opened for the season October 4. The president, Dr. Newton A. Powell. delivered the annual presidential address and gave some hitherto unpublished history of the emergency branch of the new Toronto General Hospital. which is to be known as the Shields Emergency Hospital. through the generosity of Misses Agnes and Jane Shields in memory of their late brother, Mr. John Shields.

Chicago Health Exhibit in Canada.—The exhibit of the Chicago Health Department which was taken to the Canadian Exposition, Toronto, is to be exhibited in all the schools of Canada, by request of the governor-general. Canada is also sending a health train and exhibit throughout the dominion.

Tuberculosis in Quebec.—In the report of the Royal Commission on Tuberculosis for the province of Quebec, which has just been published, it is seen that the deaths in that province from this disease are not decreasing. The death-rate in Quebec is higher than in Ontario or any of the adjacent states. It remains stationary in Quebec, while in other countries where a well organized campaign is conducted it is reduced 40 to 50 per cent. The death-rate in the rural districts nearly equals that of the cities and most of the victims range between the ages of 25 and 40 years. It is estimated that Quebec is losing annually $2,000,000 as a result of tuberculosis.

Personal.—Dr. David M. Lineham, Glenboro, Manitoba, and Dr. McGillivary S. Fraser, Brandon, have been placed in charge of the medical work on the Hudson Bay Railroad.——Dr. M. A. Lindsley has been appointed professor of pathology and bacteriology, and Dr. D. Fraser Harris professor of physiology and histology in Dalhousie University, Halifax. Arrangements have also been made with Dr. George L. Sinclair for a course of lectures on mental diseases, and with Dr. Montague A. B. Smith for a course in clinical and practical medicine. ——Dr. Ernest Jones, Toronto, has returned from Germany where he read a paper before the International Congress of Psychologic Therapeutics.——Dr. John George Adami, Montreal, is returning from Rome. He has recently been elected president of the Montreal City Improvement League.——Dr. John L. Day, Montreal, is recovering from an appendicitis operation.——Sir Watson Cheyne, England, accompanied by Dr. George S. Strathy, Toronto, has been on an extensive canoe trip in northern Ontario.——Dr. W. J. Hunter Emory, Toronto, was tendered a complimentary banquet by the staff of Grace Hospital, at the Toronto Club, October 6. He has left for southern California, where hereafter he will reside and devote his attention to fruit farming.——Dr. Herbert S. Birkett and Dr. Ethier, Montreal, have returned from Europe.

LONDON LETTER

(From Our Regular Correspondent)

London, Oct. 7, 1911.

Dangers in the Manufacture of Patent Fuel with Pitch

Patent fuel made by mixing pitch with small coal in a proportion varying from 8 to 10 per cent. is produced on a large scale. The mixture is first reduced to dust in disintegrating machines heated sufficiently to melt the pitch and finally pressed into molds to form briquettes. This operation has been certified by the government as dangerous and, as the result of an inquiry, regulations have been proposed dealing with the manufacture. The danger arises from the action of pitch fragments or pitch dust on the eyes and skin of the workmen. The dust causes irritation of the eyes and ulceration of the cornea, while on the skin it produces dermatitis and warts. The warts, primarily non-malignant, become epitheliomatous. They are found on the arms and scrotum. The ingredient of pitch which causes the warts has not yet been ascertained; anthracene has been suggested. It is proposed to prevent dust in the factories by encasing the elevators and disintegrating machinery, and to protect the workmen from dust by the wearing of overalls, and by the removal of the dust from the skin by bathing and washing at the works. The wearing of goggles is to be compulsory.

The Opening of the Medical Sessions at the London Hospitals

The formal opening of the winter session has taken place at the London Hospital by the usual introductory addresses. A large amount of reorganizing and rebuilding has taken place during the last year and is still in progress. Guy's School is largely rebuilt and within twelve months will be second to none in equipment. New chemistry and physics departments have been erected and the physiology department has been considerably expanded. Elaborate arrangements have been made for research in all these subjects. An entirely new building is being equipped for pathology, while the dental department is being greatly extended. At St. Thomas Hospital a school of physical exercise and massage has been opened, under the charge of Mr. R. Timburg, a graduate of the yal Gymnastic Central Institute, Stockholm. At the London Hospital considerable additions have been made to the dental school and a beginning has been made in providing a students' hostel.

The Insurance Bill and Voluntary Hospitals

At the annual conference of the British Hospital Association, the president, Sir William Corbett, chairman of the Manchester Royal Infirmary, stated that the insurance bill, while not diminishing the work which the voluntary hospitals have to do, would seriously diminish their income by tapping the two main sources of income—the employer and the working man. Each of these would be taxed under the bill for sickness and, therefore, would be less inclined to subscribe voluntarily for the same object. He suggested that the hospitals should receive payment for the insured patients whom they treated.

A Babies' Boarding House

A novel and most useful institution, St. Mary's Nursery College, has been founded in London by Mrs. Bernard Mole. It may be called a babies' boarding house run on original principles. This college fulfils two objects: It trains efficient girls who desire to become children's nurses, and it affords a much-needed home to motherless or uncared-for babies. There are crèches, orphanages and similar institutions to assist mothers of the poorer classes who may be obliged to go out to work, or the widower left helpless with young children. But until this college was founded the fact was overlooked that a similar need exists in higher classes. There are professional women who have to continue to work after marriage, and also widowers who have no means of having their children properly cared for. While doing this the college provides an excellent training for girls who desire to become children's nurses; for these there is a great demand. As the children range in age from 2 weeks to 7 years, extensive experience can be gained. The girls are instructed in the dietaries suitable for babies at different ages, nursery cooking and the cutting out and making of children's clothes. Classes are also held in nursery hygiene, physiology, first aid, kindergarten occupations, games and songs. If the student passes through her course satisfactorily she is entitled to wear the uniform of the college. The fee for six months' training (including board and lodging) is $180.

London's Next Lord Mayor a Doctor

In the coming year, for the first time in its history, London will have a doctor for Lord Mayor. The recipient of the honor is Sir Thomas Crosby, M.D., the alderman next in rotation. He has been for many years engaged in practice in this city.

Hydrophobia From a Fox Bite

A death from hydrophobia contracted in an extraordinary way—from the bite of a fox—has just been the subject of an inquest. Some months ago the deceased was bitten on the hand, through a thick woolen glove, by a hunted fox at the end of a run. He dismounted from his horse, drove back the hounds and held the fox. While doing this he was bitten. He made no complaint about the bite and mentioned it only casually to his friends. He died on the fourth day of his illness and only twenty-eight hours before death did symptoms of hydrophobia become manifest.

Vital Statistics

According to the fifty-eighth number of a most useful publication, the *Statistical Abstract for the United Kingdom*, which has just been issued and contains figures for the fifteen years up to and including 1910, the death-rate of England and Wales has fallen from 17.1 per 1,000 in 1896 to 13.5 in 1910. At the same time marriages have fallen from 15 to 14.3 per 1,000 and the birth-rate from 29 to 25. During this period there has also been a great increase in emigration. In 1896, 57,547 Britons emigrated to British colonies and 104,378 to foreign countries, chiefly the United States. Last year 249,499 emigrated to the colonies, of whom Canada received 156,990 and Australasia 45,701. For the first time on record more went to Canada than to the United States, although the number to the latter was above the average, 132,192. Increasing temperance is shown in the decline of spirits consumed. In 1900, this amounted to 37,000,000 of proof gallons; in 1910 to only 24,000,000 in spite of the increase of population. During the same period the amount of beer consumed fell from 36,000,000 to 32,000,000 barrels.

The Employers' Liability Act

The Employers' Liability Act of 1906 was passed with the sole object of benefiting the workman who might be injured in his employment without any regard for the principles of justice and has been a fertile cause of malingering and litigation. Like other benevolent legislation passed without regard for economic laws it has proved in some ways a hardship to the very class it was designed to benefit. It tells against a large section of workmen suffering from some slight physical disability which in no way increases the risk of accident and causes employers or insurance companies to protect themselves by refusing to engage this class. It is therefore more difficult for men past middle age who have some slight physical incapacity to find employment. The burden imposed by the act is serious, for it extends not only to the legal dependents of an incapacitated or deceased workman but to his illegitimate dependents, to embrace child, grandchild, parent and grandparent. It has even been held that a posthumous illegitimate child comes within its scope. The most unjust feature of the act is that the employer is liable for death or disability even though it results from wilful and serious misconduct on the part of the workman. Thus, if a mason goes to work intoxicated and falls from a scaffold, the employer must pay. Another extraordinary feature of the act is its discrimination in favor of manual over brain work. A "workman" signifies one who earns his living by manual labor, but it also applies to any one who works under an employer by way of clerical work or otherwise and whose remuneration does not exceed $1,250 per annum. Above this a man who works with his brain is excluded, but a man who works with his hands is included though earning any amount.

Condensed Milk as a Food for Infants

Under the direction of the local government board. Dr. F. J. H. Coutts has investigated the use of condensed milk as a food for infants and has issued an important report. He has found that machine-skimmed milk, condensed milk, is used on a considerable scale. Though the label on the tin declares, as is required by law, that the milk is "machine-skimmed," poverty tempts the mother to buy it and in some cases it seems that the term is imagined to be some guarantee of purity, as the milk is supposed not to be touched by hand. Others imagine that the term implies that the tin contains milk rich in cream which has been skimmed from the top. Sometimes the term "machine-skimmed" is in small type on an obscure part of the label. All these things tend to confuse the purchaser and lead to failure to recognize the real meaning of the warning. Dr. Coutts recommends that tins containing skimmed milk should bear the words "Unfit for Infants." As to the value of whole condensed milk, there is considerable difference of opinion, but Dr. Coutts thinks that there is a tendency to exaggerate the evil effects of feeding on full-cream condensed milk.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Sept. 29, 1911.

Fourth International Conference of Eugenics

The Fourth International Conference of Eugenics which has just been held in Paris, has drawn general attention to this science, which, although it has been in existence only about ten years, has already given valuable results in the study of production of domestic animals, grains and plants. Recognition has thus been given to the great importance for biology of the very curious facts discovered about fifty years ago by the Austrian monk, Gregor-Johann Mendel, who being a devoted amateur gardener, performed many experiments in the crossing of plants, especially peas. The results of these experiments, published in a little-read book, remained unnoticed until 1900, when three naturalists studying independently the variation of heredity, Hugo de Bries, Correns and von Tschermak, were led to discover the work of Mendel. New researches soon confirmed what were thereafter called Mendel's laws. Are the principles of genetics destined to enter rapidly into the domain of perfecting races? Certain enthusiastic savants seem to think so. Some skepticism on this point, however, seems justified. Materials are still lacking to permit the categorical assertion that Mendel's laws apply to man and in particular to pathologic heredity in man. It is, however, in man that the study of the problem meets the greatest difficulties. Experiment is of necessity excluded; and moreover the animal and vegetable races are more pure than the infinitely hybrid nations of the west of Europe and the United States. Moreover, it is possible to know only a few human generations: in the space of thirty years one may have thirty generations of peas but hardly two generations of man.

An interesting communication on the mechanism of the variation of races and the molecular transformation which accompanies these variations was made at the conference by Dr. Armand Gautier, professor of chemistry at the Faculté de médecine de Paris. The theories of Lamarck and Darwin do not account for the abrupt and apparently spontaneous modifications which are often noticed in plants and animals when they are observed in sufficient numbers. According to Professor Gautier these abrupt variations are the principal origin of races. They may be attributed to two preponderant, if not exclusive, causes. 1. The action of a foreign fecundating plasma on the vegetable or animal ovule. 2. The symbiosis of vegetative plasmas belonging to different races, sometimes to different species, but adapted to enter in coalescence, that is, to grow and to functionate in intimate union with the plasmas which they modify. The modifications thus caused are not gradual but sudden. They even transform the chemical constituents of the new plant or animal. Gautier is disposed to believe that it is by sudden variations of this kind that the various animal and vegetable species are formed with their present intervals and their reluctance to mingle.

M. Louis Blaringhem of the Sorbonne, explained the plan formed by Dr. Roux, director of the Pasteur Institute, to study various temperaments and their resistance to diseases. A close relation seems to exist between diseases and the coloring of individuals. Guinea-pigs in this respect present interesting peculiarities. Experiments were undertaken at the Pasteur Institute to obtain pure strains of red, gray, black and white guinea-pigs. It appeared that white guinea-pigs are very prolific and produce more females than the red, but they are also much more susceptible to [non-infectious] diseases than the red, although more resistant to infectious diseases.

The Rôle of Military Physicians in the Pacific Penetration of Morocco

Dr. Toubert, chief physician of the army and former director of the sanitary service at Casablanca, has just published an interesting article on the pacific penetration of Morocco by medical action. At Morocco the practice of the indigenous medicine and pharmacy is absolutely unrestrained. There is a distinct line between the indigenous medicine and surgery. Surgery is, as it was once in France, in the hands of barbers. They are skilful in the use of cupping-glasses and understand the good effect of the cautery well applied. Medicine, in the hands of empirics and especially in the hands of the marabouts, consists in the prescription of common plants and various minerals and especially in the distribution of little sachets containing paper covered by Arabic figures which act mysteriously by long contact with the diseased part. Under these conditions it is easy to understand that the often ready success of modern medicine and surgery rapidly inspire the Moroccans with confidence in our military physicians, and this all the more, since the greater number of physicians attached to the French consulates are young military physicians called to these responsible posts because of the knowledge of the indigenous medicine which they have acquired in Algeria and in particular their knowledge of the Arab language and of the psychology of the Mussulman races. The civilizing influence of France in Morocco finds a powerful aid in public sanitation and hygiene. In this respect the military physicians find valuable collaborators among the natives of high rank and Moroccan functionaries with whom they have had occasion to form professional relations on coming to Casablanca, and who are generally much impressed by a visit to the campaign hospital at Casablanca. When it becomes necessary to combat small-pox, exanthematous typhus and recently, the plague, the powerful collaboration of these former patients was always received by the physicians.

Physical Culture in the Army

Impressed by the unsatisfactory gymnastic records of the candidates recently received at the military school, M. Messimy, minister of war, has decided to raise the physical requirements in the examination for admission to these schools. He insists that the physical culture of future officers ought to be carried to the same point as their general culture. The minister is taking an interest, moreover, in developing physical culture in the army, especially among the officers.

An Anti-Alcoholic Federation Among Workmen

The scourge of alcohol, to which for a long time the working class has been very indifferent, has begun to interest them. There has been recently organized a Fédération ouvrière anti-alcoolique, which is sending out an appeal to all the syndical organizations inviting them to take part in anti-alcoholic propaganda. The federation has already held several meetings and given moving picture lectures in Paris.

Cholera in Tunis

The sanitary situation of the region of Tunis is at present inspiring great uneasiness. Cholera which appeared in some place in the suburbs has now penetrated into the Arab city. Up to the present the epidemic has made victims only among the Jews and natives; the Europeans have been exempt.

Deaths

Dr. H. C. Lutz, *agrégé* libre of the Faculté de médecine de Paris, and Dr. Louis Grandeau, former dean at the Faculté des Sciences de Nancy and professor of agriculture at the Conservatoire national des arts et métiers, have just died at Paris.

Creation of a Pasteur Institute at Algiers

A Pasteur Institute has just been established at Algiers, the technical and administrative direction of which is undertaken by the Pasteur Institute of Paris. This direction has been entrusted to Dr. Calmette. The scientific make-up of the new institute comprises a service for rabies, a service of bacteriology applied to medicine, an antimalarial service, a service of agricultural microbiology and a veterinary service. The site on which the new buildings are being constructed covers an area of about 2½ acres, in one of the most beautiful spots in the suburbs of Algiers. The architecture of all the buildings is of the simplest, without any costly decoration, and the details of the interior arrangement have been carefully studied so that the expense of the undertaking may be reduced to a minimum, and also with an eye to furnishing all the desirable conveniences for future workers in the laboratories. Thoroughly equipped laboratories are close at hand to each service. Daylight is plentiful everywhere, and the grouping of the laboratories on the northeast side of the building prevents the sunlight from being an annoyance in the microscopic work. One interesting detail is that all the outside openings are covered with brass wire netting, and each door is protected on the inside by a screened vestibule, so as to make it impossible for any fly or mosquito or other winged insect to get inside.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, September 28, 1911.

Personal

Professor König of Greifswald has been elected as successor of Professor Friedrich who goes to Königsberg as director of the surgical clinic.

Agreement Between Germany and Great Britain in the Campaign Against Sleeping Sickness

A few weeks ago an agreement with reference to the combating of sleeping sickness in the protectorate of Togoland and in the Gold Coast Colony was effected between Germany and Great Britain. As the basis of the agreement, both governments shall investigate and keep each other informed of the incidence, extent and spread of sleeping sickness in the regions mentioned and shall treat persons affected with the disease and take precautionary measures against this disease in proportion to the means at the disposal of the governments of the territories involved. The two governments shall also have the right to restrain commerce at the frontier by such measures as seem necessary to hinder the spread of sleeping sickness but are required to communicate to each other without delay the measures adopted. The agreement which has been concluded for three years takes effect December 1 of this year and is to remain in force for an additional year so long as notice is not given by one or the other party six months before the expiration of the period of validity.

Sectarian Objection to the Acceptance of a Medical Hospital Intern

Last year an unpleasant sensation was aroused by the fact that the director of a hospital, situated in a suburb of Berlin, refused to accept a medical "praktikant" intern of the Jewish faith, who had announced his desire to take his "practical year" in that institution before obtaining his degree, the refusal being based on the assertion that the director's assistants refused to have anything to do with a Jewish medical "praktikant" and that he must refuse the appointment in order to avoid conflict. There is some doubt whether the director was in the position to restrain his assistants from expressing their antisemitic feelings and to lead them to a better view. At any rate it was very unwise in him to inform the "praktikant" of this reason for his refusal. This view was also expressed in the medical press and in the Berlin-Brandenburg medical council (*Aerztekammer*), and it was also the subject of a complaint against the director addressed to the board of managers of the hospital, but all without reaching any result.

A short time ago the executive committee of the Prussian medical council (*Aerztekammer*) addressed a communication to the imperial chancellor with reference to this matter, requesting that he should officially publish a statement that it was not permitted to a hospital to refuse a "praktikant" intern for sectarian reasons. The answer of the imperial chancellor just published is as follows: "In the decree for the order of examination of May 28, 1901, it is not contemplated that the obligation to accept every candidate who applies shall be imposed on hospitals which are entitled to receive 'praktikant' interns. There seems to me to be little occasion for official interference with the widest freedom of choice as to application and acceptance on the part of candidates as well as of the hospitals; because the number of places for 'praktikants' in Prussia is more than double that of the candidates who have passed the examination, and therefore it is possible for every candidate to find a place for his practical year to correspond to his legitimate wishes. Any official action of the character desired would only have the effect of bringing sectarian matters into the field of medical education which is naturally neutral. I would prefer therefore to refrain from any action in this direction." In the professional journals this answer of the imperial chancellor is unfavorably criticized, but I cannot see the validity of this criticism. In fact there are enough places for all these candidates and it will never happen that a director of a hospital will be compelled to accept a "praktikant" who is not agreeable to him. [The term "praktikant" as used here refers to those students who have passed their examination, but are required to spend a year in some hospital before receiving their license to practice.]

International Tuberculosis Conference

An important meeting took place under the presidency of Prof. B. Fraenkel for the discussion of international tuberculosis questions, in which a number of domestic and foreign members of the international tuberculosis conference participated. It was decided to hold the next international tuberculosis conference in Rome, April 11 to 13, 1912, and to discuss as the most important questions, human and bovine tuberculosis, specific treatment, and the participation of woman in the campaign against tuberculosis. Also measures are to be taken to protect the symbol of the international tuberculosis association, the double red cross, against misuse. Twenty-eight countries belong to the association.

An Italian Fake Scientific Academy and Its Dupes "Honorary Members"

For some years from time to time, to the entertainment of the initiated, it is announced in the medical and daily press that a more or less well-known physician has been elected an honorary member of the Italian Physio-Chemical Academy of Palermo. These announcements are made repeatedly, although it has been pointed out in the professional press that this concerns a downright swindle by two Italian sharpers. These sharpers are speculating, not unsuccessfully, in vanity, and even prominent professors in German universities have become their victims. Now cruel fate has brought it about that one of the most noted and successful Berlin quacks has also been chosen as an honorary member of the academy, and this distinction has naturally been inserted among his other advertisements. The Berlin chief of police has consequently taken occasion in an official notice to show the true character of the academy. The *Deutsche medizinische Wochenschrift* in giving a notice of this announcement adds the [illegible] this announcement will at least prevent [illegible] physicians or such as would like to be sc [illegible] to the Italian swindle. The warning published already years ago in our weekly and other medical journals and later repeated has not been sufficient to hinder even university professors from accepting this 'honorary membership.' The noted Berlin quack in question, has published a list of his brother members in this academy in a statement in reply to the warning of the chief of police. Each of those whose names are found in this list may well complain with Gretchen: *Mir tut es in der Seele weh, dass ich mich in dieser Gesellschaft seh.* 'It pains me to the soul to find myself in such company.'"

VIENNA LETTER

(From Our Regular Correspondent)

Vienna, Sept. 24, 1911.

The Third Meeting of the German Urologic Society in Vienna

This society convened in Vienna on September 17 and lasted three days which were devoted to a great deal of scientific and other valuable work. The president, Professor Zuckerkandl (Vienna), welcomed the guests, who were also entertained at a concert by the doctors' orchestra of Vienna. A notable feature of this congress was the absence of the usual distracting social diversions, which have been deplored so often after previous congresses. In the unanimous opinion of all present the work done was of a high character. The part played by the Vienna school of urologists and anatomists was very brilliant, but the internists of this city were conspicuous by their passive attitude. A *Festnummer* of the *Wiener medicinische Wochenschrift*, containing numerous articles by eminent surgeons, was distributed among the members and received much attention. The committees for the next meeting (which will take place in 1913 in Berlin) were elected on the last day; von Koranyi and Oberländer were made vice-presidents, while Casper was elected president in place of Zuckerkandl. Only a few of the more interesting chapters of the transactions will be mentioned. Great attention was paid to the discussion on "Permanent Results of Removal of Tuberculous Kidney," which was introduced by Israels (Berlin) and Wildbolz (Berne). Both surgeons urged the necessity of removal of the diseased kidney as early as possible, provided the other kidney be normal. Tuberculin should not be employed, as it might hasten the course of disease, or cause valuable time to be lost in waiting. The majority of those present were in favor of these measures and from the figures mentioned in the discussion it appeared that the mortality following the operation is low, the benefit to the patient high, the prognosis good in early cases. Blum mentioned that tuberculous meningitis is a much more frequent complication of tuberculosis of the kidney than, for instance, of pulmonary phthisis.

The discussion following Casper's paper on prostatectomy was of great interest. The authors agreed as to the comparative safety of the operation, even in very aged persons (80-88 years), provided that no septic focus had already weakened the patient excessively. Regarding the method of operation, each surgeon has to find out which way suits him best, although Freyer's enucleation seems to be the most reliable one. Certain connections between the prostate and diabetes were studied by Necker (Vienna). Dr. Götzl (Prague) has made experiments relating to anaphylaxis caused by repeated injections of testicular extracts. He has found that the relations between man and animal are of the nature of specificity of organs, but not of the genus, or in other words, that the extract of a human testicle acts on the animal in the same way as the extract of the animal's testicle. He therefore expects that it will be possible to influence the human organism by extracts from animals' testes.

The present position of the urologist in regard to urethroscopy was discussed by Oberländer (Dresden) and Wossidlo (Berlin), and in regard to cystoscopy by Paschkis (Vienna) and Gross (Vienna). These two diagnostic methods are at present indisputable and must be used in every case, especially where the symptoms are masked, but they seem to be a little neglected by surgeons on account of the results obtained by kidney surgery. The value of vaccines was illustrated in a paper by Dr. Reiter (Berlin), who found them very useful in *B. coli* infections of the urinary organs of grown-up persons, less so in children. Bilharziasis was demonstrated and discussed in a paper by Dr. Pfister (Cairo), who also showed several specimens from ancient Egypt, proving that the disease was known in those times when a special goddess of Bilharzia was worshiped in Upper Egypt.

A very valuable addition to the papers was the demonstration, by Professor Tandler, of anatomic preparations dealing with the organs in question. These demonstrations were made in his anatomic laboratory, and the dissections elicited the unanimous admiration of the audience. Especially the relations of the female ureter to the uterus, and the changes to which it is subject during pregnancy, were most clearly visible. And with these demonstrations the congress came to an end.

Miscellany

REINFORCED COTTON WADDING

A New Material for Use Under Plaster-of-Paris Dressings

Robert D. Maddox, M.D.
CINCINNATI

I have had made, for use under plaster-of-Paris dressings as a protective or padding, a new material, which, judging from the experience of others and myself, I find to meet the desired conditions more nearly, and to be, because of its cheapness, convenience, elasticity and accuracy of application, superior to anything that may be had at present for this purpose, with the exception of stockinet and felt, as especially indicated.

This material is essentially a good grade of cotton wadding starch-glazed on one side, which is reinforced by attaching to the other side a coarse gauze by means of starch size, so as to form a double-faced fabric of single thickness, one side of which is gauze, and the other cotton wadding.

The wadding is of two thicknesses, technically known as two- and four-pound weight, in order to provide a light or heavy protection as is indicated, while the starch-glazed face renders the dressing reasonably non-absorbent. In laying down the wadding, long-fibered, commercially clean cotton has been used, which gives a resilient elasticity and reduces packing or "caking," with subsequent loosening of the dressing, to a minimum, while making the dressing soft and non-irritating. The cost of this material will probably be about the same, weight for weight, as that of the ordinary cotton batting or sheet wadding that is now used and less than that of canton flannel. For convenience, the rolls have been made 6 yards long by 36 inches wide, from which pieces of suitable widths, usually 3 to 6 inches, may be cut as required by means of a sharp knife, and applied spirally as an ordinary roller bandage, face side to skin, with edges either in apposition or overlapping; or a piece may be cut of sufficient size to make a continuous covering of single thickness over the part, the edges of the material being drawn together and fastened by means of a needle and thread.

The length of the piece so cut should be slightly longer than that of the plaster in order that it may be turned back and caught by the last turns of the plaster bandage to finish the top and bottom of the cast. A preliminary report of this material was deemed necessary, owing to the fact that, through error, some of this reinforced wadding made for experimental purposes was sold before the experimental work was completed.

I have made, experimentally, a similar combination of starch gauze and sterile cotton, surgically clean and highly absorbent, and believe it to be an ideal material for all forms of surgical dressings, particularly in conditions in which heavy dressings are required.

Comparative Chances of Life of the Sexes.—A noted English statistician has calculated that of two children, a boy and a girl, born on the same day, the boy will have only seventeen chances against eleven of living one year, while the girl will have twenty-one chances against eleven. From the age of 5 to 15 there appears to be but little difference, but from 15 to 19 the critical period in the life of the female, the boy will have 269 chances and the girl 277 chances of living against one of death. This advantage in favor of the female increases, especially from 35 to 75, when the ratio drops slightly till after 80, when the man will have only three chances of life against one of death, while the woman's chances will be much greater.—Stewart in *Medical Record.*

The Power of Heredity.—"He who inherits a predisposition to insanity," says Maudsley, "does not necessarily get it from a parent who happens to be insane—no, not even though his father was insane when he was begotten, or though in madness his mother conceived him. He gets it from where his parent got it—from the insane strain in the family stock."

Marriages

John Mason Little, M.D., Boston, Mass., to Miss Ruth Esther Keese of Ashburnham, Mass., at St. Anthony, N. F., October 1.

W. L. Delevan, M.D., to Miss Alfretta Bingley, both of Hagerstown, Md., at Martinsburg, W. Va., October 3.

Grosbeck Walsh, M.D., Cristobal, C. Z., to Miss Nancy Irvin of Ohio, in San Francisco, August 29.

William Oscar La Motte, M.D., Riverside, N. J., to Miss Sue C. Hall at Finksburg, Md., October 11.

Charles J. Skwor, M.D., Milladore, Wis., to Miss Rose Hennen of Fond du Lac, Wis., October 3.

William J. C. Lamb, M.D., to Miss Marie Antoinette Keller, both of Homestead, Pa., October 4.

Frederick Garrison, M.D., Baltimore, to Miss Catherine Soper, at Elkridge, Md., October 4.

John H. Morrison, M.D., to Miss Coila Myers, both of Kansas City, Mo., September 26.

Robert Russell Hollister, M.D., to Miss Susan Holdrege, both of Omaha, Neb., October 4.

John Albert Seabold, M.D., to Miss Delphine McMenamy, both of St. Louis, October 2.

Leo G. Bartels, M.D., to Miss Pauline Becker, both of St. Louis, October 1.

Deaths

Christopher C. Reid, M.D. Albany (N. Y.) Medical College, 1864; a member of the Medical Society of the State of New York; one of the founders of the Oneida County Medical Society, and first president of the Rome Medical Society; examining surgeon for the New York Central Lines for twenty-five years, consulting physician to the Rome Hospital and one of the incorporators of the Rome Home for the Aged, Indigent and Infirm; donor of the Nurses' Home and the new operating room to the Rome Hospital; died at his home in that city, aged 72.

Moses Craft Lathrop, M.D. Worcester (Mass.) Medical College, 1852; a member of the American Medical Association; said to have been the first surgeon in New Hampshire to operate for appendicitis; assistant surgeon of the Nineteenth Iowa Infantry; surgeon of the Fourth Engineers and Corps d'Afrique—Ninety-Eighth United States Colored Infantry—during the Civil War; president of the Dover Medical Society and vice-president of the New Hampshire Medical Society; died at his home in Dover, September 28, aged 81.

Neal Mitchell, M.D. Long Island College Hospital, N. Y., 1880; of Jacksonville, Fla.; a member of the American Medical Association, and formerly president of the Duval County (Fla.) Medical Society; a member of the state examining board for the fourth judicial district and of the Duval County Board of Health; a pioneer practitioner of Jacksonville and one of the heroes of the yellow fever epidemic of 1888; died at his summer home in Readfield, Me., September 30, from tuberculosis, aged 55.

Daniel Dechert, M.D. University of Pennsylvania, Philadelphia, 1871; for one term treasurer of Schuylkill County, Pa., and for twenty years coroner and deputy coroner; county medical inspector for the State Board of Health; a member of the Schuylkill County Medical Society; died at his home in Schuylkill Haven, October 4, from uremia, aged 65.

Charles William Spayd, M.D. U. S. War Board, 1861; University of Pennsylvania, Philadelphia, 1866; surgeon of the Fifty-Third Pennsylvania Volunteer Infantry, during the Civil War; physician of Luzerne County, Pa., from 1867 to 1872, and coroner from 1881 to 1884; died at his home in Wilkes-Barre, September 29, from diabetes, aged 71.

Luther M. Perkins, M.D. Missouri Medical College, St. Louis, 1886; a member of the Washington State Medical Association; formerly a member of the faculty of his alma mater and a member of the staff of the St. Louis City Hospital; died at his home in Tacoma, September 27, from locomotor ataxia, aged 56.

Benjamin Moody, M.D. Geneva (N. Y.) Medical College, 1868; Jefferson Medical College, 1869; a member of the Medical Society of the State of Pennsylvania; a veteran of the Civil War and for several years a school director of Mansfield; died at his home in that place, September 22, from nephritis, aged 69.

William Edwin Bonawitz, M.D. College of Physicians and Surgeons, Baltimore, Md., 1889; of Millerstown, Pa.; a member of the Medical Society of the State of Pennsylvania; died in Johns Hopkins Hospital, Baltimore, October 2, a few hours after an operation for the removal of gall-stones, aged 45.

Orrin Davis, M.D. Eclectic Medical Institute, Cincinnati, 1846; said to have been the oldest alumnus of that institution; for fifty years a practitioner of Attica, N. Y., and a professor in various eclectic medical colleges; died at his home in Sawtelle, Cal., September 27, aged 88.

Joseph Hervey Reynolds, M.D. Bellevue Hospital Medical College, 1864; a member of the American Medical Association; one of the oldest residents of Allegheny County, Pa.; a member of the staff of the Presbyterian Hospital, Bellevue; died at his home in that city, September 28, aged 89.

Arthur H. Thompson, M.D. New York Homeopathic College, New York City, 1861; the oldest practitioner of Lapeer, Mich.; four times mayor of the city and president of the local U. S. pension examining board; died at his home, September 26, from cerebral hemorrhage, aged 73.

Calvin Knox Smith, M.D. Rush Medical College, 1876; of Fort Washakie, Wyo.; a member of the American Medical Association; physician at the Shoshone Indian Reservation for twenty-five years; died at his home, October 1, from valvular heart disease, aged 57.

Henry Spring Strickland, M.D. College of Physicians and Surgeons, New York City, 1877; of Olympia, Wash.; a member of the Washington State Medical Association; died at the Minor Hospital, Seattle, September 23, from malignant disease, aged 58.

John W. Medaris, M.D. Willoughby (O.) University, 1845; (license, Indiana, 1897) a member of the Indiana State Medical Association; for fifty-three years a practitioner of Brookston; died at his home, September 21, aged 97.

E. C. Adams, M.D. Hahnemann Medical College, Philadelphia, 1886; of Duluth; formerly of Minneapolis; died in Duluth, April 7, from the effects of poison believed to have been self-administered with suicidal intent, aged 55.

Gilbert Gaudreau, M.D. Medical School of Maine, Brunswick, 1889; secretary of the Augusta (Me.) Board of Health; died at his home in that city, September 25, after an operation for appendicitis, aged 57.

Jesse Linnord Sammons, M.D. Starling Medical College, Ohio, 1885; a member of the American Medical Association; died at his home in Calis, W. Va., September 30, from cerebral hemorrhage, aged 52.

Camillo H. Machinek, M.D. Howard University, Washington, D. C., 1892; a member of the Medical Association of the District of Columbia; died in his apartments in Washington, October 3, aged 40.

Clarence L. Nichols, M.D. Hahnemann Medical College, Philadelphia, 1885; a specialist on diseases of the eye and ear; died at his home in Portland, Ore., September 26, from anemia, aged 50.

Eugene P. Lanthurn, M.D. Pulte Medical College, Cincinnati, 1882; of Stockton, Cal.; died in the San Joaquin County Hospital in that city, September 28, from tuberculosis, aged 53.

Sherman B. Hitt, M.D. Medical College of Ohio, Cincinnati, 1886; health officer of Greensburg, Ind.; died at his home in that city, September 26, from *angina pectoris*.

Davis Jefferson Foster, M.D. University of Nashville, Tenn., 1859; a Confederate veteran; died at his home in Paducah, Ky., October 1, from senile debility, aged 80.

Alexander M. Shields, M.D. University of Louisville, Ky., 1883; of Chaplin, Ky.; was shot and instantly killed in an affray at Chaplin, September 29, aged 56.

Andrew A. Allison, M.D. University of Tennessee, Nashville, 1888; of Edna, Tex.; died in a sanitarium in Houston, Tex., September 12, aged about 50.

John H. Walker, M.D. Miami Medical College, Cincinnati, 1868; died at his home in Oak Ridge, Mo., September 29, from heart disease, aged 71.

James E. Mahoney (license, Wisconsin, 1904), a practitioner since 1898; died at his home in Milwaukee, September 27, from heart disease, aged 45.

Isaac L. Kip, M.D. New York University, New York City, 1854; died at his home in New York City, October 6, from senile debility, aged 81.

Joseph Blakie Bishop, M.D. Washington University, St. Louis, 1866; died at his home in Athens, Tex., April 4, aged 73.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION.

CALCIUM PHENOLSULPHONATE (SULPHOCARBOLATE)

Report of the Council on Pharmacy and Chemistry

A subcommittee of the Council submitted this report:

The Council having voted to consider the eligibility of calcium phenolsulphonate (calcium sulphocarbolate) for inclusion with New and Nonofficial Remedies, the product as it is found on the market was examined in the chemical laboratory of the American Medical Association, with a view of establishing standards for this substance. The laboratory now submits its findings in the matter which show that, largely as a result of its efforts, a product of satisfactory quality is now on the market.

The phenolsulphonates (sulphocarbolates) are, probably, not very valuable as therapeutic agents. Calcium phenolsulphonate has little to recommend it over the official sodium phenolsulphonate, and it may be held as an unnecessary duplication of an official substance; yet its provisional inclusion in New and Nonofficial Remedies is recommended since it contains two radicals (the calcium and the phenolsulphonic) often given in certain conditions, and it may for that reason be found to have some advantage over sodium phenolsulphonate. Further, if the product be described in New and Nonofficial Remedies and standards of purity for it provided, this will have the effect of improving the quality of the product on the market.

It is recommended, therefore, that calcium phenolsulphonate (calcium sulphocarbolate), with the description herewith submitted, be accepted as a non-proprietary article, and that the products of the Abbott Alkaloidal Co. and of the Mallinckrodt Chemical Works be listed.

In order that physicians may appreciate the work of the Association's chemical laboratory and recognize the influence which it exerts on the improvement of the quality of medicines, it is recommended that publication of this report and of the report of the chemical laboratory be authorized.

This report was adopted and in accordance therewith the description of calcium phenolsulphonate appears on another page of this issue and the report of the chemical laboratory is published below.

W. A. PUCKNER, Secretary.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE AMERICAN MEDICAL ASSOCIATION]

CALCIUM PHENOLSULPHONATE

W. A. Puckner and L. E. Warren

The examination of calcium phenolsulphonate (calcium sulphocarbolate) was taken up at the request of the Council. Tentative standards for the substance were prepared and after the examination of the specimens had been completed, these standards were submitted for criticism to several manufacturers of chemicals. At the same time the findings (for each manufacturer's product) which were not in accord with the proposed standards were submitted to the manufacturers interested.

The product was examined with reference to the residue on ignition, loss on drying at 100 C., freedom from arsenic and heavy metals, sulphates and uncombined phenol. Some of the specimens studied were purchased on the open market while others were furnished by the manufacturers. The tests for purity to which the product was subjected are as follows:

TESTS

An aqueous solution of the salt (1-100) should not respond to the time-limit test for *heavy metals* prescribed by the United States Pharmacopeia, 8th Revision.

An aqueous solution of the salt (1-100) acidified with a few drops of diluted hydrochloric acid should give no immediate turbidity after the addition of 1 c.c. of barium chlorid test solution (limit of *sulphate*).

If 5 gm. of the salt be percolated with 25 c.c. of ether in a small filter, the solvent allowed to evaporate spontaneously and the residue, if any, dissolved in 5 c.c. of water, the solution should not give a white precipitate on the addition of a few drops of bromin test solution (absence of *phenol*).

If dried at 100 C. (212 F.) for 1 hour the salt should not lose more than 2 per cent. of its weight (absence of an undue amount of *water*).

If from 0.5 to 1 gm. of the salt be dried to constant weight at 100 C. (212 F.) and the dried substance be slowly ignited in an uncovered crucible (care being taken that the contents be freely exposed to the air) until the weight becomes constant, the residue should amount to not less than 35.0 per cent., nor more than 36.0 per cent. of the weight of the dried substance.

The results of the examination[1] are tabulated below.

These results show that commercial calcium phenolsulphonate varies somewhat in purity and uniformity of composition. The formula commonly assigned to the salt in most text-books of pharmaceutical chemistry is $Ca(C_6H_5O_4S)_2+H_2O$. Theoretically such a salt should contain 4.45 per cent. of water and should yield 33.68 per cent. of residue on ignition. The above formula is given in Merck's Index (1907), yet the market product bearing the label of this firm was found to contain only 0.45 per cent. water and was therefore, not the monohydrated salt indicated by the formula.

The results of our examination were then transmitted to the firms whose products had been examined.

The Mallinckrodt Chemical Works, in replying, wrote that its manufacturing department was experimenting in an attempt to produce a phenol-free salt at moderate cost. Some time later a specimen of this firm's latest product was sent to the laboratory for examination. This specimen lost 0.44 per cent. of its weight on drying and the dried material yielded 35.24 per cent. of residue on ignition, results that were well within the limits suggested in the standards proposed. The specimen did not respond to the bromin-water test for phenols and both in color and odor was superior to the first specimen of this firm's that was examined.

The Abbott Alkaloidal Co., in submitting its brand of calcium phenolsulphonate, gave the same formula to indicate the composition of its product as is found in Merck's Index, namely, $Ca(C_6H_5O_4S)_2+H_2O$. When the specimen was dried at 100 C., however, it lost about 15 per cent. of its weight, showing that it had a much larger water-content than was claimed by the manufacturer. This result was verified also by the amount of residue found on ignition, which amounted to 30 per cent. of the weight of the undried specimen instead of 33.68 per cent. as is required by the formula of the salt containing 1 molecule of water. These laboratory findings

Brand.	Water (Loss at 100 C.).	Residue on Ignition (Calculated from Dried Specimen).	Color.	Odor.	Phenol Test.
M. C. W.[2]	0.42	35.18	Noticeably pinkish	Somewhat phenol-like	Distinct precipitation.
M. & Co.[3]	0.45	35.28	Very faintly pinkish	Distinctly phenol-like	Distinct precipitation.
A. A. Co.[4]	15.13	35.24	Faintly yellowish	Distinctly acetone-like	None.
P. W. R.[5]	0.41	35.42	Faintly pinkish	Odorless	Distinct precipitation.

[2] M. C. W. = Mallinckrodt Chemical Works.
[3] M. & Co. = Merck & Company.
[4] A. A. Co. = Abbott Alkaloidal Company.
[5] P. W. R. = Powers-Weightman-Rosengarten Company.

---

[1] The details of the analysis will be sent on receipt of a stamped envelope; they will also be published in the Annual Report of the chemical laboratory.

were sent to the firm. No acknowledgment was received for nearly six months and then the company wrote questioning the chemists' results and asserting that its product contained "about 4.5 per cent." (theoretically 4.45 per cent.) of water instead of the 15.1 per cent. as had been reported by us. This, of course, was a reiteration of the claim made at the time the product was submitted to the Council. In its letter, the company stated that it was sending another sample of calcium phenolsulphonate for further experimentation. This specimen lost 1.93 per cent. of its weight on drying and the dried material gave 35.15 per cent. of ash on ignition; it did not respond to the bromin-water test for phenol. These later results indicated that, although the firm was ignorant of the composition of its own product, the second specimen complied with the proposed standard.

As the table shows, the products of Merck and Powers-Weightman-Rosengarten were both found to contain free phenol. These firms were advised of the laboratory's findings, but, beyond acknowledging the letters that were sent, they have taken no further action.

The results of the examination of calcium phenol-sulphonate illustrate what other examinations in the Association laboratory have so often shown, viz., that commercial products which are but little used and for which there are no authoritative standards for strength and purity, are also invariably unreliable in composition.

CONVICTIONS UNDER FOOD AND DRUGS ACT

In spite of the handicaps to which the Bureau of Chemistry has been subjected by the enemies of the pure food law both within and without the Department of Agriculture, many vicious frauds both in foods and drugs have been exposed and their perpetrators punished. The records of these cases are published by the Department of Agriculture in a series of leaflets known as "Notices of Judgment." Unfortunately these publications, like most government documents, do not reach the general public although they may be had for the asking. Recognizing this fact, The Journal has at different times abstracted the information given in the Notices of Judgment in an attempt to popularize this important work. The matter thus published has been reprinted both in pamphlet form[1] and in "Nostrums and Quackery"[2] making it available for public distribution.

Unfortunately not all the details that have been brought out in the various government investigations appear in these Notices of Judgment. When they were first issued, the information given was much more complete, but as Solicitor McCabe's influence gradually overshadowed the Bureau of Chemistry the data published by the government in the Notices of Judgment became more meager until only the barest facts now appear in these publications. As will be remembered, at the investigation recently made of the Bureau of Chemistry, it was shown that McCabe not only "edited" the various Notices of Judgment before publication but, in at least one case, falsified the record apparently to avoid hurting the feelings of those food manufacturers that find it necessary to use benzoate of soda in their products! This week we publish brief abstracts of a few more cases of interest not only to physicians but also to the public.

MUNYON'S REMEDY

Every reader of newspapers knows of Munyon—of the pompadour and uplifted finger. For years this quack has been humbugging the public but Nemesis in the form of the Bureau of Chemistry finally overtook him. Some time ago Munyon's Homeopathic Home Remedy Company shipped at different times two consignments of its nostrums. The first consignment was labeled "Munyon's Asthma Cure," which was said to "permanently cure asthma." The government chemists analyzed this "cure" and found it to consist of sugar and alcohol. The second consignment contained two preparations one of which was labeled "Munyon's Special Liquid Blood Cure, Price $2.00." Some of the claims made for this nostrum were:

> "Eradicates Syphilis and Scrofula from the Blood, and acts as a tonic to the general system.
>
> "It cures enlarged tonsils or glands, ulcers and all forms of sores and eruptions.
>
> "It cures Syphilitic Diseases of the Bones, syphilitic ulcers, syphilitic and scrofulitic skin diseases, removes all impurities from the blood, and tones up the whole system."

This was analyzed in the Bureau of Chemistry and found to contain a trace of corrosive sublimate, the balance being about equal parts of potassium iodid and milk sugar.

The other preparation in the same consignment with "Munyon's Special Liquid Blood Cure" was "Munyon's Blood Cure." The claims for the latter were:

> "Munyon's Blood Cure will positively cure all forms of Scrofula, Erysipelas, Salt Rheum, Eczema, Pimples, Syphilitic Affections, Mercurial Taints, Blotches, Liver Spots, Tetter and all skin diseases."

It would also do several other things—according to Munyon. Analyzed by the government chemists this marvelous remedy was found to consist of sugar! All of these preparations were declared misbranded because of the false therapeutic claims made for them, for at the time this case was before the courts the Supreme Court had not emasculated the Food and Drugs Act. In other words, Munyon was charged with lying about his sugar pills and similar nostrums. He pleaded guilty and was fined $200 in each of the three cases.—[*Notice of Judgment, No. 874.*]

QUININ WHISKEY

The Quinin Whiskey Company, Louisville, Ky., shipped in interstate commerce some of its product "Quinin Whiskey." In addition to claiming certain medicinal properties for this preparation, the label bore the following statement:

> "Alcoholic strength 85 per cent. Quinin 1¼ grains per ounce. Guaranteed under the Food and Drugs Act," etc.

Analyzed by the chemists at Washington, it was found to contain only 42 per cent. of alcohol instead of 85 as stated on the label and instead of having 1¼ grains of quinin to the ounce it contained only 1/75 of a grain. Naturally the stuff was declared misbranded. The defendant pleaded guilty and was fined $25 and costs.—[*Notice of Judgment, No. 885.*]

INDIAN TAR BALSAM

John B. Hurtt and Thomas D. Hurtt of Baltimore, who did business under the name Indian Tar Balsam Company, shipped some of their product into the District of Columbia. It was said to be:

> "The never failing remedy for the cure of coughs, colds, sore throat, and all kinds of throat and lung affections."

When analyzed, it was found to consist of about 60 per cent. of oil and 40 per cent. of water, the oil floating and being partly volatile, with an odor of tar, and the water containing morphin derivatives. As the labels bore no statement regarding the quantity or presence of morphin or its derivatives and as the claims for its curative properties were false and misleading, the stuff was declared misbranded. The defendants pleaded guilty and were fined $25. [*Notice of Judgment, No. 898.*]

STANGE'S GENUINE ANTISPASMODIC OR CRAMP DROPS

This nostrum was made by E. J. and Minnie Abel of Chicago and the labels purported that the article was a cure for spasms, cramps, vertigo, pressure on the heart and other things. Analysis showed it to contain alcohol, ether and oil of peppermint. As such a mixture would not cure the various disorders mentioned on the label and as no statement regarding the amount of alcohol and ether appeared on the bottle the nostrum was declared misbranded. The Abels pleaded guilty and were fined $25 and costs.—[*Notice of Judgment, No. 903.*]

---

[1] The pamphlet, "Convictions Under the Food and Drugs Act," is sold at 6 cents the copy.

[2] "Nostrums and Quackery," press of the American Medical Association, price $1.00

BRADBURY'S CAPI-CURA

Bradbury's Capi-Cura was a so-called headache cure sold by James J. Cramer who did business as the Cramer Drug Company of Boston. The preparation was of the usual acetanilid type but contained no statement on the label indicating the presence of this dangerous drug. It was therefore declared misbranded and on Cramer's pleading guilty a fine of $25 was imposed.—[*Notice of Judgment, No. 906.*]

SEPTICIDE

Septicide was an impudent fraud made in Milwaukee and sold as a cure for practically everything from "cancer" to "chapped hands," and from "suppressed menstruation" to "sweaty feet." It was a nostrum of the typical "cure all" type. When analyzed by the government chemists it was found to consist of water with small quantities of sulphur dioxid and sulphuric acid and a trace of nitrates. As Dr. Wiley's assistants got after this vicious fraud before the Supreme Court decision crippled the pure food law, it was possible to convict the Septicide Company of misbranding. Orange Williams, secretary and treasurer of the concern, pleaded guilty to the falsehood and the court imposed a fine of $10.—[*Notice of Judgment, No. 907.*]

NYAL'S HEADACHE WAFERS

This is another nostrum of Frederick Stearns & Co. of Detroit. Each of these "headache wafers" contains 4 grains of acetanilid and 1 grain of caffein alkaloid. In spite of the presence of these powerful drugs, the label stated:

> "It does not produce any bad after effects nor does the system become habituated to its use so as to produce a noxious drug habit."

The stuff was declared misbranded first, because the word Nyal was fictitious; second, in that it was not a cure for headache; third, because it would produce bad after effects, and fourth, because it would also produce a noxious drug habit. Wayland Stearns, second vice-president of Frederick Stearns & Co., entered a plea of nolo contendere and was fined $2.—[*Notice of Judgment, No. 908.*]

INFALLIBLE HEADACHE TABLET

This was another acetanilid product and was made by the Infallible Headache Co., Columbia Cross Roads, Pa. It was said to be an infallible cure for a number of conditions for which it was not a cure and it was further claimed "neither will they cause heart failure." On both counts they were declared misbranded. The defendant pleaded guilty and paid a fine of $25 and costs.—[*Notice of Judgment, No. 919.*]

(*To be continued*)

Correspondence

A Conjecture Respecting the Cause of Beriberi

To the Editor:—I was much interested in reading the article commenting on beriberi in The Journal (Oct. 7, 1911, p. 1213). I am sorry to say that I cannot agree with the theory of beriberi being caused only by white milled rice. Beriberi is, of course, a true neuritis, and phosphorus is certainly removed in taking away the outer layer of the rice paddy, but my experience was that when proper precaution was taken in harvesting and caring for the rice after harvest —storing it in a dry place—that there was very little or no beriberi. Witness the Danish captain in the Siamese navy who personally told me that he had never had a case of beriberi on board his ship in seventeen years' service, and who personally bought the best rice and was careful as to its storage in a dry place: also the fact that beriberi usually is epidemic in the far East in jails, asylums, tin mines and barracks, where proper care is not taken in storing the rice in a dry place. My own experience covers many thousands of cases and on investigation I always found that the rice-supply had been stored in a wet or damp place. Among the best Siamese families, who live largely on a rice diet, beriberi was almost unknown, but their servants living in the basements of their palaces, where rice was stored in a damp place, suffered greatly from the disease. Also, beriberi is far more prevalent after a very wet rainy season when the cultivators have had trouble during and after harvest to keep their rice dry. This was shown at Chiengmai, in the north of Siam, several years ago, where, after the wettest season in twenty years, there was an epidemic of beriberi and hundreds of people died of the disease. Now, these people in the far North do not use the white milled rice but the rice husked in their crude pounding mortars which retain almost all of the outer layers of the paddy, and yet they contracted the disease by taking the rice which is supposed to prevent it and which contains the phosphorus needed. Also, on the side of the river where the ground was higher and the floods less, there was very little of the disease, but on the side where the floods were great the disease raged fiercely.

I simply submit my observations which covered five years of time and many thousands of cases.

Charles S. Braddock, New York.
Late Chief Medical Inspector Royal Siamese Government.

The Treatment of Rhus Poisoning

To the Editor:—I wish to report on a treatment for ivy poisoning used with success on three persons, two patients and myself. Since boyhood, I have been subjected to at least yearly poisoning from ivy, sometimes most severely, and naturally I tried all the "sure cures" of the laity and, after studying medicine, all the treatments found in medical literature.

Last August, however, I tried, as a palliative measure to allay the itching and irritation, a standard commercial solution of formaldehyd as put up in pound bottles, and obtained immediate and lasting relief. The first application, made in the morning, to the hands and arms, caused no pain; the second application, made in the afternoon, to the scrotum, caused intense pain which disappeared, however, after cold applications for ten or fifteen minutes. A patient whose eyelids were involved was relieved after one application. To keep the solution from the conjunctiva and cornea, petrolatum was placed on the free border of the lids, among and $\frac{1}{8}$ inch beyond the cilia. After the solution was applied and had become dry, petrolatum was applied all over the eyelids, to prevent formaldehyd vapors getting into the eye. Wet cotton pledgets were placed in each vestibule; a wet towel was used to keep the fumes from the mouth. In another patient, whose hands and side of face, including the external ear and canal, were involved, there was no pain from the treatment to hands and face but there was considerable pain from the application to the ear. This, however, passed off and no other treatment was necessary. It occurred to me afterward that a weaker solution would have been just as effective to the scrotum and external canal of ear. After five or six days I used hydrogen peroxid to the parts painted, which removed the dry and somewhat discolored skin, leaving a perfectly smooth surface.

C. E. Purcell, M.D., Paducah, Ky.

Maggots in the Ear

To the Editor:—With reference to a report on "Screw Worms in the Ear" (The Journal A. M. A., Oct. 7, 1911, p. 1207), I wish to report the following: A patient showed me a maggot which, he said, had crawled out of his left ear during the night; he also complained of sleeplessness for the two preceding nights on account of pain in his ear. I discovered a white, wriggling mass behind the isthmus of the external canal. After several unsuccessful attempts to remove this mass by various methods, I resorted to a 4 per cent. solution of cocain, which removed eight maggots, making a total of nine from one ear. The entire canal and membrana tympani were severely inflamed. Recovery was uneventful.

John A. Huth, M.D., Natrona, Pa.

Queries and Minor Notes

Anonymous Communications will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

INDICAN IN THE URINE

1. *To the Editor:*—Please give reference to an authoritative work on the presence of indican in the urine, its cause and the diet necessary for its elimination. W. Fletcroft, Paterson, N. J.

2. *To the Editor:*—Please describe a method for the quantitative estimation of indican in the urine.
L. W. Howe, Coldwater, Mich.

Answer.—1. We do not know of any work treating this subject specially. It is discussed in books on clinical diagnosis and on physiologic chemistry.

2. There is no very good method for the determination of the amount of indican in urine. A colorimetric method is sometimes used, in which the indican is set free and converted into indigo by the action of an oxidizing agent, such as calcium hypochlorite (chlorid of lime), or Obermayer's reagent, which consists of a 0.2 per cent. solution of ferric chlorid in concentrated hydrochloric acid. The coloring matter thus produced is extracted by chloroform and the color of the chloroform extract compared with a standard blue color, such as indigo or Fehling's solution. The following approximative method has been recommended: To a hundredth part of the whole day's excretion add an equal volume of Obermayer's reagent and 5 c.c. of chloroform. Shake a minute or more and allow to settle. Compare the color with that of a strong Fehling's solution, taken as 100, as a standard.

WASSERMANN REACTION

To the Editor:—1. To what extent is the Wassermann reaction positive in locomotor ataxia?

2. How does this percentage compare with that of the reaction in undoubted syphilitic disease? Henry Power, Spokane, Wash.

Answer.—1. It is impossible to give a definite answer to this question. It will probably vary from 65 to 90 per cent., taking the various workers the world over. The reaction in locomotor ataxia is less frequently positive than in secondary untreated syphilis or in cases which present demonstrable syphilitic lesions of the nervous system.

2. In very early syphilis, the primary stage, the Wassermann reaction is low—perhaps 60 per cent. In marked secondary untreated syphilis the reaction is high—practically 100 per cent. In late nervous syphilis, paresis and syphilitic brain disease the percentage is high—90 to 100 per cent. In locomotor ataxia as named above. In late syphilis of the bones, gummatous degeneration of the skin, etc., the reaction again is low—50 to 60 per cent. The location of the lesion, the duration of the disease, and especially whether it has been or is being treated, may modify the reaction, either positively or negatively.

NO MORE COPIES OF REPORT OF CHICAGO VICE COMMISSION

To the Editor:—Can you tell how I may secure a copy of the report of the Chicago Vice Commission to which you have referred several times in The Journal? L. A.

Answer.—In our review of this book (June 10, 1911, page 1743) we gave the street address of the commission. The chairman of the commission recently wrote us: "The edition of the report is exhausted and there are no more copies for distribution. The commission has completed its labor and has gone out of existence."

PYROLIGNEOUS ACID AND RHEUMATISM

To the Editor:—Please state whether or not pyroligneous acid is of any therapeutic value in the treatment of rheumatism, gout and neuritis, and if so the dosage, method of administration, etc.
V. D. Washburn, Wilmington, Del.

Answer.—Pyroligneous acid is simply a crude wood-vinegar containing about 6 per cent. of acetic acid and presumably would have as much value as a therapeutic agent as acetic acid or vinegar.

PLANS WANTED FOR COMBINED RESIDENCE AND OFFICE

To the Editor:—I am proposing to build a combined residence and office. On looking for a book of plans that would be suggestive I fail to discover any such book, and I have not been able to get in touch with any published plans that bear on this class of buildings. Certainly many physicians have put up such houses and it is barely possible that some of your many readers may be able to give me some hints. H. M. Ferguson, Morris, Ill.

SALVARSAN ACCIDENTS

To the Editor:—Kindly give me references to reports of deaths from the intravenous injection of salvarsan.
Edwin Walker, Evansville, Ind.

Answer.—The following are references to fatal cases or cases accompanied by alarming symptoms:

Finger, E.: By-Effects of Salvarsan, *Berl. klin. Wchnschr.*, May 1, 1911; abstr. in The Journal, June 10, 1911, p. 1765.

Martius, K.: Fatalities After Injection of Salvarsan in Cardiovascular Disease, *München. med. Wchnschr.*, May 16, 1911; abstr. in The Journal, June 24, 1911, p. 1909.

Leven: Mishaps with Intravenous Salvarsan Injections, *Med. Klinik*, May 28, 1911; abstr. in The Journal, July 1, 1911, p. 54.

Mann, C.: Salvarsan Accident, *München. med. Wchnschr.*, Aug. 1, 1911; abstr. in The Journal, Sept. 9, 1911, p. 935.

Fischer, B.: Case of Fatal Hemorrhagic Encephalitis Following Injection of Salvarsan, *München. med. Wchnschr.*, Aug. 22, 1911; abstr. in The Journal, Sept. 30, 1911, p. 1171.

Kannengiesser: Fatality Following Injection of Salvarsan, *München. med. Wchnschr.*, Aug. 22, 1911; abstr. in The Journal, Sept. 30, 1911, p. 1171.

Hoffmann, A.: Jaundice with Fatal Outcome After Salvarsan Treatment, *München. med. Wchnschr.*, Aug. 15, 1911.

PAPER-BAG COOKERY

To the Editor:—Please give information about paper-bag cookery and where particulars concerning it may be obtained. L. H. K.

Answer.—It is asserted that by this method of cooking many articles, such as meats, fish, poultry, birds, many vegetables, fruits, cereals, pies, cake and other desserts and even soup, may be cooked in paper bags, with the advantage of retaining all the flavors of the foods, and with no subsequent labor in washing the cooking utensils. The present method seems to have been developed by Nicolas Soyer, a chef of London, whose exposition of the method, together with recipes for preparing many dishes, is contained in a small book published in England and obtainable through book-dealers in this country at 60 cents. Any bag may be used, but the food is apt to taste of the paper, so bags of specially prepared paper have been made.

CARBON DIOXID IN KELOIDS

To the Editor:—Can you inform me, through your Queries and Minor Notes column, as to the value of carbon dioxid crayons in the removal of keloids? Are the keloids any less apt to return following their removal by this method than after their removal by the knife?
C. C. H.

Answer.—Hoffman and others have had good results in keloid from freezing with solid carbon dioxid, but the method has not had enough trial to be certain of the ultimate results. Pusey, who cites Hoffman (*Jour. Cutan. Dis.*, July, 1910) does not believe the results from solid carbon dioxid are likely to be as good as those obtained from *x*-rays. Removal of keloids by excision is as a rule unsuccessful and is not advisable; they return larger than before.

OLEOZONE — SEROTHERAPY OF TYPHOID

To the Editor:—We have a doctor here who is claiming to cure pulmonary tuberculosis. His treatment consists of the use of Ozonoid tablets put up by C. S. Roberts, New York City. Please give me any information you can regarding these tablets.

2. Please give me the latest literature on the serum and vaccine treatment of typhoid fever.
J. W. Lindley, M.D., Natoma, Kan.

Answer.—1. Ozonoid tablets is one more name for a much-christened fake to which The Journal has given a good deal of space. Its first name was Hydrocine. When analyzed in the Association's laboratory, the chemists reported that they found that "each 29.5 gr. Hydrocine tablet contains 28 gr. of cane sugar, small quantities of volatile oils and a trace of pancreatin." The stuff originated, it seems, with one C. E. Getsinger, who organized what was known as the Medical Food Company. The commercial possibilities in selling an odoriferous sugar-mixture as a "consumption cure" apparently appealed to one Charles S. Roberts, a physician of Syracuse, N. Y., who, with the help of Charles H. Goddard, and others, incorporated the Hydrocine Company for the purpose of exploiting Getsinger's "treatment." Goddard, it will be remembered, was the man who organized that cooperative "patent-medicine" concern known as the A. D. S.—the American Druggists Syndicate—of which Roberts was one of the officers. Getsinger and Roberts later seemed to have had a disagreement and the former marketed his own product under the name of Oxydase. Roberts changed the name of Hydrocine to Oleozone and apparently had the stuff made by the A. D. S.

—at least it bore the same serial number as that given the A. D. S. products. Coincident with these changes in the name, another concern came into existence—the Cowles Institute, said to be operated by one H. L. Cowles. This also dispensed "oxygenated products" for the cure of consumption. A little later Cowles seems to have changed the name of his concern to the Hemavitæ Company and to have rechristened his product Hemavitæ.

The latest change in the name of Getsinger's product is Oxidaze, put out by the American Oxidaze Company. This company claims to have purchased the formula of Getsinger, who is no longer connected with the business. The concern is, we understand, controlled by a group of business men, although one of the individuals connected with it—Eugene Howard—is said to be a physician. Roberts, apparently, is still selling the stuff under the name Oleozone. In a revised price-list, sent out by Roberts a few days ago, he notifies the users of his nostrum that the price of Oleozone has gone up. As he puts it: "Increase in the cost of some of its basic constituents has made necessary a slight advance in the price of Oleozone." Thus, it appears that housewives are not the only sufferers from the increased cost of sugar.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Oct. 14, 1911.

Chase, C. L., M.R.C., relieved from duty at Fort Oglethorpe and ordered to Fort Dade, Fla., for duty.

Whaley, A. M., captain, arrived at Fort Monroe, Va., for duty.

Reddy, J. J., lieut., left Fort Jay for temporary duty at Fort Wood during absence of Lieutenant Pascoe.

Stone, F. P., D.D.S., ordered to visit certain posts in Department of Gulf from Oct. 15, 1911, to July 1, 1912. (S. O. 31, Oct: 1, 1911, E. D.)

Hart, W. L., on arrival at San Francisco from the Philippine Islands will proceed to Fort Sam Houston, Texas, for duty.

Clayton, G. R., M.R.C., reports his departure from Fort Sheridan, Ill., on leave of absence for one month and ten days.

Mount, J. R., M.R.C., arrived at San Francisco en route to Schofield Barracks, H. T.

Duncan, W. A., captain, reports return to medical supply depot Washington, D. C, from leave of absence.

Eastman, William R., captain, left medical supply depot, New York, for Fort Riley, Kan., for duty.

Shockley, M. A. W., major, on arrival at San Francisco will proceed to Fort Niagara, N. Y., for duty.

Webber, H. A., major, on being relieved by Major Shockley will proceed to Fort Logan H. Roots, Ark., for duty.

Feely, J. F., A.D.S., ordered to Fort Slocum, N. Y., for duty.

Sherwood, Charles E., A.D.S., ordered to Columbus Barracks, Ohio, for duty.

Siler, J. F., *captain, relieved from duty at medical supply depot,* New York, about Nov. 5, 1911, and ordered to Fort Sam Houston, Texas, for duty.

Thomason, H. D., captain, will proceed to Trenton, N. J., about Oct. 17, 1911, in connection with the reorganization of the militia of New Jersey.

Webber, H. A., major, granted leave of absence for one month, about Oct. 14, 1911.

Bowen, A. S, lieut., arrived at Fort Snelling, Minn., from San Antonio.

Wolven, F. H., D.S., arrived at Vancouver Barracks from Fort Liscum, Alaska.

Boak, S. D., D.S., reports his arrival at West Point, N. Y., from leave of absence.

Woodbury, J. H., major, left Fort Screven on detached service at Atlanta.

Mason, G. L, D.S., left Fort Snelling for Fort Omaha, Neb.

Maus, L. M., colonel, returned to his station, Chicago, from leave of absence.

Medical Corps, U. S. Navy

Changes during the week ended Oct. 14, 1911.

Stitt, E. R., surgeon, detached from the bureau of medicine and surgery, navy department, and ordered to duty at the naval medical school, Washington, D. C.

Riggs, C. E., surgeon, detached from the naval academy and *ordered to the Wabash.*

Evans, S. G., surgeon, ordered to the naval academy.

Gill, J. E., P. A. surgeon, detached from the *Wabash* and ordered to the *Des Moines*

Hough, F. P. W., P. A. surgeon, detached from the *Des Moines* and ordered home to await orders.

Wheeler, W. M, surgeon, ordered to the naval hospital, Washington, D. C., for treatment.

Brownell, C. DeW., surgeon, ordered to duty as senior medical officer at the navy-yard, Portsmouth, N. H., and to additional duty in command of the naval hospital at that place.

Beeching, C. L, asst.-surg., ordered to duty under instruction at the naval medical school, Washington, D. C.

Hayes, O, A. A. surgeon, ordered to the marine recruiting station, Denver.

Asserson, F. A., surgeon, ordered to duty at the naval hospital, Boston.

Holloway, J. H, P. A. surgeon, ordered to the naval hospital, Las Animas, Colo., for treatment.

U. S. Public Health and Marine-Hospital Service

Changes for the fourteen days ended Oct. 11, 1911.

Perry, J. C., surgeon, detailed to represent the Service at the Fifth International Sanitary Conference of American Republics to be held at Santiago, Chile, Nov. 5-12, 1911.

Anderson, J. F., P. A. surgeon, detailed to represent the Service at the meeting of the National Committee on Milk Standards *to* be held under the auspices of the New York Milk Committee in New York City, Oct. 4-6, 1911.

McLaughlin, A. J., P. A. surgeon, directed to proceed from Chicago to Topeka, Kan., on special temporary duty.

Rucker, W. C., P. A. surgeon, detailed *to represent* the Service at the next annual meeting of the Mississippi Valley Medical Association to be held at Nashville, Tenn., Oct. 17-19, 1911.

Salmon, T. W., P. A. surgeon, granted six months' leave of absence, without pay, from Oct. 18, 1911.

Pettyjohn, Joseph, P. A. surgeon, granted two months' leave of absence from Sept. 16, 1911.

Frost, W. H., P. A. surgeon, directed to proceed to Cincinnati and Covington, Ky., on special temporary duty.

Bryan, W. M., P. A. surgeon, granted seven days' leave *of* absence from Oct. 3, 1911.

Grimm, R. M., asst.-surgeon, detailed to represent the Service at the next annual meeting of the Medical Association of the Southwest to be held in Oklahoma City, Okla., Oct. 10-12, 1911, and the Mississippi Valley Medical Association to be held in Nashville, Tenn., Oct. 17-19, 1911.

Bingham, E. O., acting asst.-surgeon, granted fifteen days' leave of absence from Oct. 7, 1911.

Cheney, E. L., acting asst.-surgeon, granted fourteen days' leave of absence from Oct. 12, 1911.

Coffee, J. H., acting asst.-surgeon, granted twenty days' leave of absence from Oct. 15, 1911.

Keiller, William, acting asst.-surgeon, granted twenty days' leave of absence from Sept. 26, 1911.

Moorer, M. P., acting asst.-surgeon, leave of absence for fourteen days from Sept. 5, 1911, amended to read eleven days from Sept. 9, 1911.

Ransom, S. A., acting asst.-surgeon, granted leave of absence for a further period of one month from Dec. 1, 1911, without pay.

Underwood, F. R., acting asst.-surgeon, granted twenty-six days' extension of annual leave on account of sickness from Aug. 23, 1911

Medical Economics

This Department Embodies the Subjects of Post-Graduate Work, Contract Practice, Legislation, Medical Defense, and Other Medicolegal and Economic Questions of Interest to Physicians

THE ECONOMIC VALUE OF SANITATION

Vital statisticians and sanitarians for years have been showing the enormous toll of human life exacted each year through ignorance and lethargy. It has been said again and again that, if this loss was in dollars instead of human lives, the necessary reforms would be quickly brought about. Probably the most unique as well as the most promising feature of the present health movement is that it is being demonstrated that health is wealth, not in the old figurative meaning, but as an actual fact, and that avoidable sickness means waste and financial loss, not only to the individual but to the community. An interesting illustration of the fact is found in an article on "The Tropics and Health," by Dr. D. W. Montgomery of San Francisco, which appeared in a recent number of the *Canadian Practitioner and Review:*

"Formerly everything seemed especially arranged to make Rio a pest-hole It had a landlocked harbor with abundance of moisture, and a hot sun beating down into it. The upper classes of its population were lazy and ignorant, and its lower classes were composed of poor whites and recently emancipated slaves. It was an old Portuguese city with narrow streets, no sanitation worth mentioning, and enough mosquitoes of the right breed to infect with yellow fever a people reduced to the proper degree of receptivity by crowding, by climate, by miscegenation, and by poor food.

GARBAGE
AMERICAN MEDICAL ASSOCIATION PRIZE CARTOON SERIES
C Batchelor

SEVERAL REASONS WHY FLIES SHOULD BE UNWELCOME GUESTS.

"But Rio is clean! How was the marvel accomplished? It is due, like many a blessing, to misfortune. The misfortune was yellow fever, and the enlightenment consequent to scientific modern medicine furnished the means of combating it. The change came with the advent of bacteriology and clearer views in regard to the causes of the acute infectious fevers. As a consequence of this clearness of view, more precise international quarantine laws were enacted, and under these the trade of Rio languished, and the peculiar bitterness of this lay in the fact that the ships that were avoiding Rio de Janeiro were passing on to its rapidly growing southern rival, Buenos Aires. Envy and loss of trade finally drove the authorities into action: two broad streets, the Avenida Central and the Cinco de Marzo, were opened up through the old crowded city; a beautiful sea wall and esplanade were built along the city front; the sewerage was so treated as not to foul the waters of the bay; and the markets were put in a sanitary condition. The meat-shops are delightfully neat; and the market on the waterfront is a model of cleanness, lightness and airiness. A good corps of health inspectors make frequent house-to-house visits, and by the free use of creolin, and by prohibiting the accumulation of stagnant water in tubs or elsewhere, the mosquito pest is almost abolished. The water-supply of Rio, drawn from the neighboring hills, is good. As a consequence of these sanitary measures there has been no yellow fever in this port for years, and there is very little typhoid fever.

"The fear of death alone would never have brought about these beneficent results. The high death-rate would have been patiently borne as it had been for ages, and would have been regarded as a visitation of Providence. The blessing was achieved through a love of gain, and a fear of loss, ably supported by the neighborly envy and hatred the Brazilian bears toward the Argentino. By the help of these ignoble passions of avarice, fear, envy and hatred, results were obtained that wisdom, learning, charity and all their cognate virtues could never have accomplished."

CONTRACT PRACTICE

Report of the Committee of the Omaha-Douglas-County Medical Society

The report of the Committee on Contract Practice of the Omaha-Douglas-County (Nebraska) Medical Society, given herewith, is one of the most valuable contributions yet made to the discussion of the question. Particularly commendable is the recognition of the economic necessity underlying the retaining of surgeons by railroads and other industrial corporations, with the distinct proviso, however, that medical services should be limited to the examination and treatment of employees incapacitated directly as a result of employment, or, as is said in the government services, "in line of duty."

"We, the committee appointed by the Omaha-Douglas-County Medical Society to investigate the broad subject of contract practice, desire to state that we have given this subject careful study and discussion. Each member studied some phase of the question, and your committee as a whole has analyzed without prejudice the combined information. We herewith submit for your consideration the following conclusions:

"1. Your committee recognizes the right of industrial corporations employing labor, to engage the services of skilled physicians, surgeons and specialists at reasonable remuneration, to examine employees as to their fitness for services as well as to care for said employees in case of injury or acute sickness when on duty, or to care for those to whom the corporation may be under obligation because of accident. This is but a just and fair protection against damage suits brought by the unscrupulous. However, it would be distinctly understood that such service should not be extended to apply to any member of an employee's family.

"2. We believe that industrial corporations employing physicians, surgeons, and specialists, should limit the service of said physicians, surgeons and specialists strictly to the care of their employees during the time of actual service. We also believe that direct representatives and officials of a corporation should not be included in such medical, surgical and special attendance, or in any way construed as coming under the conditions of this class of service.

"3. We believe that all corporations furnishing medical, surgical and special attendance to their employees should do so entirely at their own expense, or, if the employees are assessed for the expense of such medical, surgical and special attendance, they should be untrammeled in the choice of their physicians, surgeons, and specialists.

"4. We believe that contract practice as applied to lodges, fraternities, benevolent, and benefit-organizations, is detrimental to the best interests of the medical profession in general and especially to the physicians employed; that it is especially unjust to all physicians who are subject to ordinary competition, and that it pauperizes the lay public and demoralizes the medical profession in general, teaching the former to expect medical, surgical and special care for practically nothing, lessens their respect for the skill and dignity of our profession, and permits designing men to traffic in and commercialize the practice of medicine.

"5. We believe that such lodge, fraternal, benevolent or benefit-organization and contract practice, as *ordinarily* in operation, is eminently unfair, because it buys medical services at wholesale from the physician, then compels him to peddle out his services at retail, and deprives him of any voice in limiting the amount of service to be rendered for the wholesale price agreed on.

"6. In conclusion, we earnestly recommend that members of our society decline in the future to accept the position of contract physician to lodges, fraternities, benevolent or benefit-organizations, not industrial in character—therefore without all liability—as well as corporation contracts that are not in harmony with these findings.

"John E. Summers.
"H. M. McClanahan.
"James M. Aiken.
"F. E. Coulter.
"B. W. Christie."

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

[Note.—The pamphlets containing the outline of the postgraduate study course for county societies for the coming year are ready for distribution. Secretaries of county societies can secure supplies by writing to the Secretary, Council on Health and Public Instruction, American Medical Association, 535 Dearborn Ave., Chicago.]

Second Month—Third Weekly Meeting

Gunshot Injuries of Head

Character of wound, wound of entrance, wound of exit, effect on inner and outer tables, effect on meninges, effect on brain substance, hydraulic and hydrodynamic pressure. Differences of effects of leaden and jacketed missiles. Effect of initial velocity and range. Medicolegal interest in pistol-shot wounds.

Symptoms: Areas of brain involved.

Treatment: Disinfection. Indications for trephining. Use of x-ray.

Intracranial Hemorrhages

Extradural Hemorrhage: Middle meningeal artery and branches. Character of wounds, by "contrecoup." Effects of hemorrhage, local and general.

Symptoms: Mental disturbances, "free interval," pulse, respiration, motor disturbances, sensory disturbances, pupils.

Treatment: In compound fracture, indications and technic. In internal hemorrhage, indications for trephining. Krönlein's "sites of election," method of localization.

Subdural Hemorrhage: Pial vessels, branches. Character of injuries. Extent of hematoma, quantity, absorption. Differentiate from supradural—(1) free interval, (2) pulse, (3) motor disturbances, (4) localizing symptoms

Intracranial Hemorrhages in the New-Born and Children[1]

Traumatic Meningitis

Etiology: Injury; micro-organisms present, mode of entrance.

Pathology: Leptomeningitis, character of exudate, extent, cortex. Pachymeningitis, changes in dura, exudate, origin. Meningitis serosa.[2]

Symptoms: Early and late. Cortical or basilar. Chills and fever, headache, pulse, nausea and vomiting, pupils, delirium, stupor, coma.

Society Proceedings

COMING MEETINGS

Kentucky State Medical Association, Paducah, Oct. 24-26.
Medical Society of Virginia, Richmond, Oct. 24-27.
Southern Medical Association, Hattiesburg, Miss., Nov. 14-16.

MEDICAL SOCIETY OF PENNSYLVANIA

Sixty-First Annual Meeting, held at Harrisburg, Sept. 25-28, 1911

The President, Dr. John B. Donaldson, Canonsburg, in the Chair

The officers elected were named in The Journal Oct. 7, 1911, page 1217.

The Care of Advanced Cases of Tuberculosis

Prof. Walter F. Willcox, Ithaca, N. Y.: The effective segregation of an increasing proportion of the advanced cases of pulmonary tuberculosis is attended by a decrease in the death-rate from that disease, no matter what other influences favorable or unfavorable may be present, and, conversely, failure to segregate these cases is attended by a stationary or increasing death-rate. The rate at which the segregation of tuberculous patients increases in any community uniformly agrees with the rate at which pulmonary tuberculosis decreases. It follows, then, that in combating the disease the main effort of public health workers should be directed toward the extension of hospital accommodations for advanced cases and the increased segregation of such cases.

DISCUSSION

Dr. W. C. White, Pittsburgh: There are certain peculiar features of advanced cases of tuberculosis which are often lost sight of and which it is essential to consider before any scheme for their care can be adopted. Advanced consumptives are sick, and provision must be made for their continuous stay in bed with adequate nursing. Our ordinary sanatoriums and institutions for the sick refuse them admission; private practitioners want to get rid of them, and boarding-houses and homes discharge them without compunction. Few of them can ever be put in such shape as to return to their former occupation, and many of them under the proper care live for many years unable to work. These patients are sources of infection if they are the least bit careless, and, submitted to the scrutiny and remarks of acquaintances, they are very apt to become careless. These patients have in most countries the rights of citizenship and can and do refuse daily to accept the opportunity open to them for institutional care for even a few weeks or months, thus making the large institutions far from centers of population of much less value than they otherwise might be. While much evidence can be adduced to show that a marked reduction in mortality in tuberculosis can be obtained without it, the efficient and practical care of patients in advanced tuberculosis is one of the important elements, if not the most important element, in our endeavor to control this disease. The law must eventually be the means by which this infection is controlled. Proper provision should be made for tuberculous patients in asylums, jails, poorhouses, orphanages, homes, etc. A third necessity is the provision of separate institutions for the care of these patients; finally, proper provision must be made for their care in their homes.

Dr. Wilmer R. Batt, Harrisburg: I am unable to accept the conclusions of Professor Willcox because the statistics which he has submitted in regard to the reduction of mortality in England and other European countries refer to the general institutional care of tuberculosis and not to advanced cases alone; owing to the migratory tendencies of tuberculosis sufferers the mortality rates in any single American city are not sufficient evidence on which to base accurate estimates of the decline of the disease from any particular item of prevention; considering the average duration of tuberculosis it is impossible to estimate the value of preventive measures which have not yet reached their full development. To provide principally for advanced cases of tuberculosis and minimize the opportunity for those suffering from the disease in the early stages can be excused only on the assumption that it is the hopeless and dying that are dangerously infective. The bacilli in incipient or moderately advanced cases are as dangerously infective as those in advanced cases and infinitely more widely distributed.

[1] Scottish Med. and Surg. Journal, June, 1906. Frazier: Trans. American Surgical Assn., 1906. Progressive Medicine, March, 1907 and 1908.

[2] Ballance: Lancet, Dec. 21, 1907.

Dr. T. B. Appel, Lancaster: The conclusions drawn by Professor Willcox seem to me to be most timely and most important. As the terminal stages of tuberculosis seem to present the greatest dangers of contagion, more effectual precautions should be taken in such cases to combat the spread of consumption. We as general practitioners know that patients come back from sanatoriums educated in the proper care of themselves, but they come back to the same insanitary surroundings and in my experience in time become careless, lose ground and in the end succumb to septic phthisis. Therefore, if better means of segregation of these poor, ignorant, hopeless ones can be obtained, their care would be much more effectual.

Blood-Pressure and Pulse-Rate in Pneumonia

Dr. H. A. Hare, Philadelphia: The favorable ratio in croupous pneumonia is one in which the pulse-rate per minute is less than the number of millimeters of mercury as shown by the sphygmomanometer. In other words, if the pulse-rate be 90 and the blood-pressure 120, the patient is doing very well. If the pulse-rate be 100 and the blood-pressure 110, he is not doing as well as before. If the pulse-rate be 110 and the pressure 110, something must be done to bring back the normal difference already referred to, and, if the pulse-rate be 120 and the pressure 110, the patient is in grave danger and will probably die unless very active treatment causes him to rally before this abnormal ratio has lasted for any length of time. The fall of pressure may be considered to be the result of the toxemia which directly affects the vasomotor centers or the walls of the vessels themselves, or it may be due to a direct effect on the heart muscle, whereby this organ is unable to pump strongly enough to maintain pressure. It is of some importance to determine, if possible, whether this fall of pressure is due to one cause or the other, for, if it be vasomotor or vascular, direct cardiac stimulation is not needful, although it is true that most vascular stimulants are also heart stimulants. On the other hand, if the heart be at fault, attention must be directed chiefly to this organ. If the vessels be at fault, the difference between diastolic and systolic pressure will be marked, the heart, if strong, sending out a forcible wave of blood in an endeavor to fill the blood-paths. If the pressure be low from a failing heart, there will be little difference between diastolic and systolic pressure for obvious reasons. There is no treatment of pneumonia but there is treatment of the pneumonia patient, and this will vary in every case.

The Care of the Insane

Dr. T. H. Weisenburg, Philadelphia: Of all the problems which are now before the profession there is none more pertinent than the care of the insane. It seems to the alienist almost nonsense that general hospitals throughout the state should take care of medical and surgical patients and refuse to take care of the insane, thus making it necessary to send them to an asylum or a private sanitarium. The time has come when it is necessary that all general hospitals should have separate wards for the care of the mentally afflicted. A bill will be introduced in the next legislature providing for the placing of all the insane of the state in state institutions with proper provision for the criminal insane, the feebleminded and epileptic. In this way the care of the insane by the various counties will be abolished. There are to be established two laboratories for the study of the causes of insanity.

(To be continued)

INDIANA STATE MEDICAL ASSOCIATION

Annual Meeting, held at Indianapolis, Sept. 28-29, 1911

The President, Dr. F. C. Heath, Indianapolis, in the Chair

The Sociologic Aspects of Syphilis

Dr. C. E. Barnett, Fort Wayne: The sociologic aspect of syphilis is a question of state concern, for syphilis not alone deteriorates the state's own subject and his progeny, but they, on account of their syphilitic degeneration, help to fill the state institutions, thus bringing a monetary factor into play. In my opinion the present publicity education on venereal diseases, for the time being, is a detriment rather than a benefit to humanity. When, however, the education finally permeates the mind sufficiently to show the dangers of inoculation and the necessity of preservation of the body against syphilis, then the good will have been done on account of education. The question of marriage when lues is present is almost entirely in the hands of the attending physician, and he is a coward if he fails to protect the innocent.

Diagnosis of Syphilis

Dr. W. F. Garshwiler, Indianapolis: The diagnosis of syphilis is based, first on certain usually well defined clinical symptoms which appear usually in regular order; second, finding in the blood-serum the organism of syphilis; third, by the therapeutic test, and fourth, by the blood-serum test of Noguchi and Wassermann. The fact that under all conditions, primary, secondary or tertiary lesions, dead or living, the spirochete usually maintains its characteristic shape, makes it easy to distinguish it from other spirilla. The therapeutic test should never be used to diagnose primary syphilis.

The secondary symptoms are usually an acute toxemia followed immediately by polymorphous skin lesions. The later secondary skin lesions are usually a relapse of the earlier secondary lesion of the skin and mucous membrane. In the secondary stage the dark field illuminator and the Wassermann test will prove of the greatest help in diagnosis. The therapeutic test has no place in the diagnosis of secondary syphilis, for the reason that the lesions tend to spontaneous recovery and that mercury and potassium iodid affect other diseases which simulate syphilis.

The diagnosis of tertiary syphilis becomes relatively more difficult by every method, except the therapeutic, the longer the time has elapsed from the secondary stage. The demonstration of spirochetes in the tertiary lesions is more difficult, on account of their lessened number, and failure to find them in lesions apparently specific proves nothing. The Wassermann test is far less reliable in the third than in the secondary stage. The therapeutic test becomes a valuable aid when other methods of diagnosis fail in tertiary lesions, and should be used only for diagnosis, and only in this stage, and not until other methods have failed.

Treatment of Syphilis

Dr. D. C. Ridenour, Peru: The treatment of syphilis falls into two divisions, (a) practical, and (b) theoretical and experimental. Under the first I follow the treatment of those who favor the administration of treatment by mouth and inunction, rather than hypodermically. Syphilis is a septicemia. I would, therefore, advocate a continuous, intermitting, eliminative treatment as the most practical. Another form of treatment which gives good results is the local inunction with mercurial ointment. Sulphur baths in conjunction with mercury are excellent. Salvarsan has proved not to be a *therapia sterilizans magna*, but it is a valuable addition to the means of combating syphilis. The hypodermic mode of treatment of syphilis is painful, in many patients excites apprehension and is bitterly objected to. Furthermore, the need of the precedent administration of cocain or morphin, as so frequently advocated for relief of the pains caused, is in itself very objectionable. It is occasionally dangerous and sometimes rapidly fatal. It is very liable to be followed by certain local complications, such as erythema, cellulitis, painful nodosities, abscess and sloughing. It cannot be carried out by the patient, but requires the attention or intervention of the physician-surgeon. However, if patients demand hypodermic treatment. I would suggest the daily injection, intramuscularly, of 30 minims of liquor potassi arsenitis, with mercury by mouth.

DISCUSSION

DR. F. B. CHARLTON, Indianapolis: There is just one reasonably effective solution in sight. We are already working for a national health organization with a chair in the cabinet, and, perhaps, when that comes about there may be something done with this question. We may get national laws by which we can handle the question of prostitution and indiscriminate relationships in a way that we cannot now. I do not see anything hopeful in dealing with it in any other way than by national legislation. There must be authority to control and authority to inflict penalties. As to diagnosis, I want to emphasize the necessity of getting the history in syphilis. I look on the taking of the proper history as one of the most essential points. Individuals have been pronounced syphilitic who never have had syphilis. This blunder is almost as pernicious as to make a mistake on the other side. As to the intramuscular injection of mercurials, this method is nearly universally accepted. We are giving mercury in its metallic form as calomel or the salicylates, and we are getting good results. Moreover, we never give cocain or morphin to control pain. There is no particular pain at the time, sometimes a little feeling of a bruise twelve hours after. What are the advantages of this method over the old one of giving a man some medicine and sending him home to treat himself? Where they get an injection once a week or ten days, we get results, for they get the medicine. The other way they get the medicine incidentally—when they think of it, and too often they forget it altogether.

As to salvarsan, I doubt whether there has ever been a drug in the history of therapeutics so extensively studied, experimentally and practically, as salvarsan. It has been shown that there are no toxic effects from salvarsan, and that the eye does not suffer. There is only one complication, and that is in atheromatous conditions when the blood-pressure is high and the vessel walls weak. It clears up certain malignant cases that never yielded to the old methods. Give salvarsan and in forty-eight hours the patient can go home to his family without any fear of infecting them.

DR. A. W. BRAYTON, Indianapolis: What shall we do in a case of syphilis? Diagnose it along modern lines, by the clinical symptoms, by the history, the organism and the Wassermann test, and then treat it according to the best of our judgment and knowledge as taught by the ancient, and, especially, the recent, history of the disease. We have come to the parting of the ways in the treatment of syphilis. We have a new addition to our therapeutics that cannot be laughed down—salvarsan. We can control our cases absolutely with mercury, if given rightly. Then why use salvarsan? Because it is safe, it acts quickly, and there is no risk (and this is the greatest value of salvarsan) of the patients infecting other individuals in twenty-four hours after taking treatment. When you come to consider the subject two or three years from now, there will be but one voice—and that will be for the intelligent treatment of syphilis by salvarsan, to protect the patient and the community.

Acute Anterior Poliomyelitis

DR. W. D. HOSKINS, Indianapolis: Within the past five years there have been reported more cases of this disease than in all the previous history of medicine. The disease has long been suspected of being contagious, and a brief summary of its recent history will undoubtedly confirm the suspicion. Bacteriologists have not yet succeeded in demonstrating any constant specific organism. The virus passes unchanged through the finest filters. The pathology of the disease has for some years been known to be a degeneration of the motor cells in the ganglia of the anterior horns of the cord. A few points remain obscure. What is the reason for the decided preference for the anterior horns? Why are certain areas of the cord, notably the cervical and lumbar enlargements, especially vulnerable? Is the degeneration in the anterior horns a primary lesion, or secondary to other parts of the pathologic process? The consensus of opinion now is that the infection is primarily a vascular one. One attack of poliomyelitis usually renders the individual immune. Second attacks have been observed, but are rare. In many mild cases complete recovery occurs. Of the epidemic cases, complete recovery occurs in about 25 per cent. The mortality in epidemics is approximately 12 per cent; in sporadic cases, 6 per cent. We hope there will soon be an immunizing serum. In the meantime, we can do something toward protecting the little ones in our care by acquiring an intelligent knowledge of the disease, making early diagnosis and preventing the spread of the infection.

DISCUSSION

DR. F. B. WYNN, Indianapolis: This subject has been brought to our attention particularly by the agitation regarding it carried on through various public health agencies; and very properly, of course, because our modern knowledge of this disease teaches us that we are dealing with an infectious disease. The problem is to recognize this disease early, and that is hard to do. I do not know until the paralysis has come. I say to these patients, drink water, flush the system, dilute the toxins, keep the bowels very free—do anything to help get rid of the toxins. That is old-fashioned practice, but in these cases I believe it is the best practice. Then isolate the patient and take proper care of the secretions of the nose, which are known to be highly infectious in character.

DR. ALBERT E. STERNE, Indianapolis: We have always had acute poliomyelitis with us. There is nothing new in its sporadic occurrence. Of course, we do not see the acute cases so often, but the subacute cases have always been with us. While I believe this disease will spread by contact, we are not absolutely certain whether we are dealing with a contagious disease, an infectious disease, or a contagious-infectious disease. I subscribe most heartily to what has been said in regard to the necessity of taking cases of this kind in hand early and watching them. But what I would like to most see is the profession awakened to the real danger of procrastination in the treatment of these conditions. We should treat this like any other deep-seated inflammation. We should prevent deformities, and we can—in cases that we see early.

DR. G. W. MCCASKEY, Fort Wayne: We do not even know enough about this disease to give it a name. It is not purely an infantile disease. It may occur in substantially the same form in adults. So, if we are going to be punctilious about the name, we must not call it infantile paralysis.

Tuberculin and Autogenous Vaccines in Pulmonary Tuberculosis

MR. R. T. PETTIT, Ottawa, Ill.: Of 2,841 patients treated with tuberculin there were 1,932 patients cured or benefited from one to seven years after discharge, or 68 per cent. In the 19,249 not treated with tuberculin, 9,614 were cured or benefited, or 50 per cent. This shows an advantage of 18 per cent. in the tuberculin-treated group, a very substantial advantage. At the Ottawa Tent Colony, the results show that the percentage of incipient cases with cure or benefit in the tuberculin-treated group is about the same as in the untreated. However, the percentage of deaths in the untreated is over twice that in the tuberculin-treated group. In the moderately advanced stage, the tuberculin treated patients show a marked advantage, and in the far advanced stage, both treated and untreated, little in the way of treatment can be done.

With regard to autogenous vaccines, while it is yet too early to come to any conclusion regarding the ultimate results, I believe that in these vaccines we have another valuable adjunct to our present methods of treatment, and I believe we are justified in stating that in tuberculin and autogenous vaccines we have two valuable assets in the treatment of tuberculosis. However, we should not neglect the more valuable hygienic and dietetic principles of increasing the general resistance for these other methods of increasing the specific resistance, but, in order to produce the best results, they should be used together.

Local Use of Tuberculin in the Treatment of Open or Surface Forms of Tuberculosis

Dr. Thomas J. Beasley, Danville: The first point in these cases is to make a positive diagnosis, which is somewhat difficult. The tubercle bacilli may be found by the microscopic examination of the exudate. In a few instances I have applied tuberculin directly to the parts involved, and if a marked local reaction occurred, it seemed fair to conclude that it was a tuberculous infection. The therapeutic dose of tuberculin, when introduced hypodermically, causes tuberculous areas to become congested for a period of several hours. By the local application of tuberculin to open or surface forms of tuberculosis we can produce a similar reaction at the seat of infection, and by careful observation and repeated applications we can maintain in the tissues involved a constant reaction by gradually increasing the strength of the solutions employed. In applying tuberculin to such large areas as are frequently presented in some of these cases, great care must be exercised that the dose be not large enough to permit of enough absorption into the system to cause a general reaction. If the dose be too large in the beginning, the tissues may become insensitive and some difficulty may be experienced in producing subsequent reaction. It, therefore, seems advisable that the initial dose be small, and it is always dependent on the extent of the area to be treated. The tuberculin is applied by using a hypodermic syringe to spray the solution over the entire surface of the diseased parts. Where deep sinous tracts are to be treated, a flexible cannula is attached to a hypodermic syringe. When the cannula has traversed to the depth of the sinus, it should be withdrawn carefully and as the withdrawal is being made, the syringe should be emptied slowly of its contents. Enough of the solution should be used to fill all openings.

Twenty-four to forty-eight hours after the first application, a marked change is observed in the parts treated, the discharge being greatly lessened. The wound is not disturbed, except for the renewal of external dressings. Forty-eight hours later the severity of the reaction begins to subside. The parts are again irrigated with a saline solution, and an increased strength of tuberculin is applied. The treatment is repeated as often as seems necessary until a cure is produced. The value of this treatment in osseous involvements is yet to be determined, but it is reasonable to expect good results in this class of cases.

MICHIGAN STATE MEDICAL SOCIETY

Forty-Sixth Annual Meeting, held at Detroit, Sept. 27-28, 1911

(Continued from page 1307)

Nitrous-Oxid-Oxygen Anesthesia

Dr. Richard R. Smith, Grand Rapids: The advantages of nitrous-oxid anesthesia are: the decreased toxic effects, shown by clearer mentality following operation, lessened vomiting, quicker recovery from operation, lack of toxemia and lessened shock. These advantages are best seen in prolonged operations, to which nitrous-oxid-oxygen is especially adapted. Patients that one would fear to operate on under ether can sometimes be operated on safely under this administration. It encourages in the surgeon gentleness of touch and thoroughness, since he is less apt to be hurried by any danger attending a long anesthesia. Do not use it in operations on very robust patients, alcoholics, patients of exceedingly nervous temperament, and in operations on the head and throat.

Physostigmin Combined with Morphin in the Treatment of Pain Following Abdominal Operations

Dr. B. R. Schenck, Detroit: At present in the postoperative treatment of patients, there is a general unanimity of opinion, except in regard to the use of morphin. Some surgeons never use the drug while others give it almost, if not entirely, *ad libitum*. The majority use it sparingly, relying on codein or heroin. Morphin would be used universally (except in cases where there is danger of masking important symptoms) were it not for its paralytic effect on the intestine and its causing vomiting. Combining physostigmin with it seems to antagonize the effect on the intestine. I use tablets containing gr. 1/6 of morphin and gr. 1/75 of physostigmin. As many hypodermics of this are given as are necessary, the bowels moving well with an enema on the third or fourth day. The discomfort of the dreaded "third day" is entirely removed. The combination tablet relieves pain as well as plain morphin and prevents gas accumulation and meteorism.

DISCUSSION

Dr. W. P. Manton, Detroit: I have used more or less extensively both morphin and physostigmin—but not the combination. It seems to me that in this day and generation the use of morphin should be done away with very largely. For probably more than twenty years I was in the habit of giving laxatives and cathartics the night before the abdominal sections, and during all that time I had frequent cases of abdominal distention, sometimes extreme. For the last six or eight years I have given up entirely the use of laxatives before abdominal operations, and as a result I have rarely had a case of distention. In those cases I have employed physostigmin with, in a majority of instances, good results, but I have never given it in large doses. Instead of morphin I have used codein phosphate almost *ad libitum*, and I find a small amount of pain and irritation resulting from the inflammation taking place from the incision in healing, and codein phosphate has controlled all the symptoms, so that nowadays I very rarely give a dose of morphin. I have no doubt that the combination of morphin and physostigmin is a good one, if you are bound to use morphin in these abdominal cases, but I think that morphin can, in a majority of these abdominal cases, be omitted.

Dr. E. M. Houghton, Detroit: It is readily recognized that morphin is, perhaps, the drug par excellence for controlling pain, but it has always been, I believe, open to the question whether to give it internally or subcutaneously, in which case it is excreted very promptly. I think that some have shown that morphin given subcutaneously is excreted back into the bowel inside of two or three minutes. Whichever way the drug is given, you get an action on the bowel and you get more or less of a paralysis and a lessened peristalsis. We know that morphin controls the pain largely because of the central action of the drug, and it seems to me that Dr. Schenck's idea that it would be wise to use physostigmin in combination with morphin rests on a good basis. In physostigmin you have something that stimulates the muscle in the wall of the intestine to contract. I believe a good many experiments have been made to show just whether it acts on the muscle fibers or on the nervous mechanism in the muscles, but so far no one has been able to pin the matter down exactly.

Dr. John N. Bell, Detroit: I would like to ask Dr. Schenck to tell us whether or not his use of physostigmin and morphin has relieved the tendency to nausea which is also so distressing after using morphin. I have used codein phosphate for some years, and it has been my experience that not infrequently, although I have given 2½-grain doses, I have still been forced to resort to morphin to relieve pain.

Dr. Richard R. Smith, Grand Rapids: The treatment of postoperative vomiting is on the table—in the giving of just as little anesthetic as possible. So it is with this matter, I believe, of postoperative pain—postoperative ileus—postoperative distention. The treatment of these begins on the table, and means a brief and gentle manipulation, and when the surgeons work with this in view real progress will be made.

Dr. B. R. Schenck, Detroit: I agree that the cause of postoperative distention and postoperative discomfort is not how you prepare the patient and treat him afterward, but how you treat him while he is on the table; but even though you treat him with the greatest respect, he is going to have some discomfort. Codein is not as good an analgesic as morphin. Regarding the nausea, although I have given three or four sixths of morphin the first twenty-four hours, I certainly think the nausea has not been any greater or perhaps less, but there are so many factors that enter here that, perhaps, we are a little prejudiced and allow our judgment to lead us to form opinions which are not correct.

The Need of a Better-Developed "Obstetric Conscience"

Dr. Charles E. Boys, Kalamazoo: By the term "obstetric conscience" is meant that development of mind which has to do with generalship and exactness of technic in obstetrics. An obstetric operation is just as important, and should receive just as much attention in regard to sterile dressings, aseptic technic and freedom from hurry or need of attendance on other work as a surgical one. A good "obstetric conscience" would undoubtedly prevent many lacerations, but is of most importance in the prevention of sepsis. We make elaborate preparations for removing an infected appendix which may have ruptured, and where the surgeon has no responsibility for the present condition of the patient but we take a clean healthy woman and allow her to become infected following a forceps delivery. The same surgical care should apply in obstetric work. The Kelley pad is a dangerous thing because so difficult to sterilize. I prefer newspapers, direct from the mills, as they are more nearly sterile.

DISCUSSION

Dr. W. P. Manton, Detroit: For a long time I have insisted on absolute cleanliness, but we know that absolute cleanliness in the ordinary house is not to be obtained. I think the time is coming when every woman who can get to a good lying-in hospital, or a good hospital where they take obstetric cases, will go to that institution. As to the Kelly pad, the doctor said he used newspapers, but he did not say that he sterilized those newspapers. I take it for granted that he did; but, of course, we all know that there can be nothing that is more likely to be germ-laden than the ordinary newspaper.

Dr. H. Wellington Yates, Detroit: As far as the Kelly pad is concerned, I disagree. I think it can be sterilized. The Kelly pad used in obstetric work should not be used in general practice at all. Too much attention is paid to mortality and figures of that kind. As a matter of fact, every once in a while you see some fellow who has had a series of some four thousand patients without one case of infection. This nonsense means that he has not had one die, and he, perhaps, may be honest in that and there can be only a few who can be honest in that. But the matter of morbidity is another question, and as a matter of fact if those cases were taken care of properly the field of gynecology would be wiped out. The question of morbidity rather than mortality is the thing that interests us most. We may only lose one once in a while, but the morbidity!

Dr. W. C. Stevens, Detroit: I like the paper pad. I have used it many years. I have the woman take those paper pads and iron thoroughly on an ironing board with a red iron, as red as she could use without scorching it. Then I have her pile those up and quilt them through and through, and it does not take many pages of an ordinary Sunday paper to turn water; then I have her roll them and put them in a chest somewhere in an unused room or attic, and fill that chest, putting in plenty of formaldehyd.

Dr. Charles E. Boys, Kalamazoo: As to the sterile condition of the paper: In the paper mill the material is, first of all, immersed for 24 hours in a strong solution of chlorid of lime, to take the color out of the rags and the paper that the paper is made of. From there it goes into a large vat of chlorid of lime for twenty-four hours more; from there it is poured on a screen and rolled through fourteen or sixteen rollers of superheated steam, and that sterilizes it. From there it rolls on the printing press, and the ink is sterile. They do not fold the papers by hand any more, and the paper is not touched at all until it gets into your door yard, and then it is unfolded. Suppose you do use a dirty newspaper or a dirty kitchen table. That is of the smallest importance, because you don't put a woman on the kitchen table, but it is always covered by something to protect her from pressure injury. You cover this up, and even if you use papers, or the Kelly pad, of course this would be covered with sterile towels which are carried along.

(To be continued)

AMERICAN ROENTGEN RAY SOCIETY

Twelfth Annual Meeting, held in Richmond, Va., Sept. 20-23, 1911

(Concluded from page 1309)

Compensating Displacements of the Thoracic Viscera in Pulmonary Tuberculosis

Dr. Charles Lester Leonard, Philadelphia: Compensation for the loss of expansion in the lungs takes place through an increase in the capacity of their normal area, or through the interposition between the visceral and parietal pleura of an area filled with air, or fluid, or both. These changes must take place in proportion to the volume of the lungs involved in a pathologic process. They are in a measure appreciable by the ordinary methods of physical diagnosis. The changes which can be noted by inspection and mensuration are, however, less marked in ratio with the extent of the disease than those within the thorax, which produce displacements or alterations in the position of the viscera. An internist connected with one of the largest institutions for the special study of tuberculosis did not believe that displacements of the viscera could occur so frequently in the earlier stages of the disease. He said that in some hundreds of post-mortems conducted at the institute they had failed to find such displacements.

These pathologic variations in the position of the thoracic viscera can be shown clearly only by the rapid roentgenograms that eliminate the heart's motion. Their exact position and interthoracic relations can only be fully appreciated by the rapid stereo-roentgenogram. In the entire series of one hundred cases, twenty-six displacements of the heart and aorta were found, with three cases of pneumothorax. In seventeen cases the heart was displaced to the right; in four to the left; and in five a rotation took place, with an upward displacement of the heart and aorta, so that the heart assumed an antero-posterior position. In two cases a superficial pneumothorax was found overlying the lower left lung, and in one case an acute hydro-pneumo-thorax of tuberculous origin was shown.

A review of the cases in the entire series shows that those cases in which no displacement of the viscera was present were early lesions, in which no fibroid change had taken place, or that the lesions were not extensive and symmetrical, or that the heart was bound down by adhesions between the pericardium and the diaphragm. The unequal elevation of the two halves of the diaphragm, Williams' sign, was present in less than one-half of all the cases, and was not present where displacements of the interthoracic viscera had occurred.

The pathologic displacements of the thoracic viscera in pulmonary tuberculosis are the result of compensation for the destruction of expansive normal lung tissue by the disease. The displacing force is the result of one or two changes, or the combination of both, or, as in the case of acute pneumothorax, from the rupture of the lung. The consolidated lung area may undergo fibroid change and contraction, the contracting tissues drawing the heart and aorta with them, while the emphysematous lung on the opposite side assists in their displacement.

In addition to the displacements which cause compression of the diseased portion of the lung, there is present in many cases an ossification of the costal cartilages and an approximation of the ribs over the affected area. The compensating displacements may be divided into four groups. Displacements of the lung by superficial pneumothoraces; displacements of the heart upward and into an antero-posterior position; displacements of the heart and aorta to the left; and displacements of the heart or heart and aorta to the right.

The Control of Fracture Work by the Roentgen Ray

Dr. Roland Hammond, Providence, R. I.: The time is near at hand when no fracture or joint injury will be considered to have been treated properly if a Roentgen examination has not been made. It is a well-recognized fact that a Roentgen plate should be taken after an attempt at reduction has been made, to see if the desired result has been obtained. Of almost equal importance is a plate beforehand, to know accurately with what condition we have to deal—a fact not appreciated by the profession at large. With the knowledge thus obtained, the reduction can often be easily made, and with but slight trauma to the parts. Many cases now subjected to open operation and plating could be treated by extension and counter-extension after the method of Bardenheuer and Graessner, with as good anatomical and functional results, and at less risk and greater comfort to the patient. In many cases which seem irreducible, plates made while the patient is under ether and after successive attempts at reduction have been made will often give the clue to the situation, enabling the reduction to be made without resorting to an open operation. Some fractures are irreducible by the above methods and an open operation is necessary. In these cases an absorbable suture material should be used, if possible, reserving wire and plates for cases in which the fragments can be held by no other means.

DISCUSSION

Dr. Arthur Holding, Albany, N. Y.: It is our duty to impress on the surgeon that this fracture work must be controlled by the Roentgen ray. Only by this means can we determine absolutely whether the approximation of the fragments is as it should be. We must not hesitate to advise the surgeon to sacrifice his pride and reset a bone. In fact, the Roentgenologist may be in the rather trying position of having to protect the surgeon and the patient. We must be careful, however, when we use the Roentgen ray while the patient is still under the ether anesthesia. I have seen several instances in which the spark has caused serious damage, even when the tube was not anywhere near the ether can or mask. The spark jumped to the iron bedstead and in that way got to the ether can, and in one case there was produced a conflagration in which the patient was injured seriously. The ether bottle should be out of the room and the can away from the patient's face before the tube is excited.

Dr. Lewis G. Cole, New York: I use bromid paper instead of a plate. One can show as much on the paper as on the plate in from two to three minutes from the time the exposure is made. The prints may be made as rapidly as can be done. This applies not only to fractures, but to foreign bodies.

Dr. George C. Johnston, Pittsburgh: The *only man* competent to treat fractures correctly is he who controls his work with the Roentgen ray. It is also necessary to examine these fracture plates stereoscopically, especially in the case of fractures of the shoulder. The orthopedist is the man to treat fractures.

Collaboration Essential in the Diagnosis of Surgical Conditions of the Kidney and Ureter

Dr. John Hunter Selby, Rochester, Minn.: This cooperative examination opens up additional possibilities, especially in that large group of abdominal cases seen in daily practice which exhibit an indefinite line of symptoms referable perhaps to the appendix, gall-bladder, stomach, duodenum, spine or genito-urinary tract, but with a strong possibility of involvement of the genito-urinary tract. Such cases require careful study, and some of them tax every means at our command before we can approach an accurate diagnosis.

In St. Mary's Hospital (Mayo Clinic), all such cases are referred to the Roentgen laboratories for examination. The routine examination in this clinic may be described as follows: A full history is taken, and a physical examination made. A twenty-four hour specimen of urine is reported on, and perhaps a gastric analysis is made—all of which may throw considerable light on the case and yet not clinch the diagnosis. The Roentgenologist is then called on to examine the case and after the proper preparation of the intestinal tract a set of stereoscopic plates of the upper abdomen, and a second set of the lower abdomen and pelvis, are made by the rapid method; that is, while the breath is held. If this examination fails to reveal any abnormalities, we have not yet ruled out the genito-urinary tract. If, then, in the light of the clinical findings and negative *x*-ray examination, the diagnosis is still under suspicion, the patient goes through a second preparation of the intestinal tract and is referred to the cystoscopist the following day. In the meantime, the original plates are studied and a consultation is held between the physician in charge, the Roentgenologist, and the cystoscopist. This, at times, furnishes the cystoscopist with much-needed information, and establishes a new working basis for the Roentgenologist, should subsequent events indicate a second *x*-ray examination. The cystoscopist now makes his thorough routine examination and he alone may clear up the diagnosis by one of his ingenious methods, and thus eliminate the necessity for the "combined examination." He may gather evidence to confirm the original *x*-ray findings or to disprove them. Again, he may find evidence of trouble that had not so far been suspected. Therefore, the indications for the combined examination depend on the original *x*-ray findings plus the findings by the cystoscopic examination.

Roentgenographic Diagnosis of Ureteral Kinks Causing Intermittent Hydronephrosis

Dr. G. M. Stover, Denver: Hydronephrosis has heretofore been recognized only in rather an advanced stage, when the dilatation of the renal pelvis is considerable. We have found, and have demonstrated by catheter tests, roentgenograms and surgical operation that there is easily recognizable a much earlier stage of this condition, to be discovered before dilatation of the renal pelvis has taken place. A certain number of patients complain of pain in one or both kidneys; a pain somewhat like that of the classical hydronephrosis, but not relieved by the sudden passage of a quantity of urine and a disappearance of the tumor and without the microscopic urinary findings of fully developed hydronephrosis; a pain suggestive but not typical of renal calculus colic, and in which roentgenographic examination for stone is negative. The symptom-complex in this class of cases has usually been rather vague in its diagnostic indications, and there have undoubtedly been many instances in which a faulty diagnosis has led to operation for conditions which were not present, the trouble being laid to an appendix, a tube, an ovary, or a gall-bladder.

In the class of cases under consideration it was found by Dr. Fowler that the injection of a comparatively small amount of solution (averaging only 14 c.c.) into the pelvis of the kidney produced a pain exactly similar to the pain from which the patient suffered; an injection of the unaffected kidney produced a pain which the patient had never felt there before, but identical with that which had been felt on the other side.

DISCUSSION ON PAPERS BY DRS. STOVER AND SELBY

Dr. Percy Brown, Boston: I had a case which, clinically, was diagnosed as a nephroptosis, but, the Dietl's crisis was out of proportion to the ptosis. I made a roentgenogram and found a kink in the ureter. A ptosis was present, but not startling.

Dr. Eugene W. Caldwell, New York City: We must encourage this cooperation between the surgeon and the Roentgenologist. We cannot hope to get the best results until we get team work. I would advise Dr. Selby to do more stereoscopic work.

Dr. Charles L. Leonard, Philadelphia: It is important to look at these plates stereoscopically. I recently located five stones in the lower ureter. The surgeon would not have found the fifth stone if I had not examined the plate stereoscopically.

Pulmonary Metastases from Papillomatous Cyst of Ovary

Dr. Hollis E. Potter, Chicago: Eight years ago a woman was operated on for papillomatous cyst of the right ovary. Regional recurrence necessitated a second and a third operation, six and five years ago, respectively. One year ago a small mass was removed from the right groin. At present there are symptoms and signs pointing to a pulmonary involvement. The roentgenogram cleared up a condition which could not be diagnosticated in any other way. Over the central portion of the left lung is a mass obscuring the heart. It apparently occupies one-half of the left side of the thorax. In the right lung is a mass the size of an orange. There is no pulsation. A diagnosis of cyst was made, but the case was considered inoperable.

Relation of Roentgen Laboratory to the Medical School

Dr. Eugene W. Caldwell, New York City: There is at present a lack of cooperation between the Roentgen laboratory and the medical college. Five or six schools are beyond criticism in this respect. Most schools have laboratories which are useless and dangerous. In many hospitals a photographer or druggist runs the *x*-ray machine. Nearly all the development in roentgenology has been made by private individuals at their own expense. The results of roentgen examination should be checked up by the roentgenologist in cooperation with the clinician and the pathologist. The hospital and the medical school should make the specialty attractive to medical men who possess the necessary qualifications to do efficient work.

The Use of the Fluoroscope as a Guide for the Bronchoscope and Esophagoscope in the Removal of Foreign Bodies

DR. C. F. BOWEN, Columbus, Ohio: The successful outcome of a foreign body case depends, first, on the diagnosis, and, second, on the method of procedure. No attempt should be made to either use the bronchoscope or the esophagoscope without having a roentgenograph close at hand, and since the Roentgen ray plays such an important part in the diagnosis and treatment of this class of cases, I believe that this work should be done by the roentgenologist himself, who has a knowledge of surgery, rather than by a surgeon with a roentgenologist as an assistant.

The Abdominal Viscera in Auto-Intoxication and Auto-Infection

DR. JOEL E. GOLDTHWAIT, Boston: In the chest and abdomen are the important viscera of the body, except the brain, and the proper relation of these organs, one to the other, determines the health of the individual. The Roentgen ray is of the greatest assistance in determining the position of these organs as well as the disturbances that may result from a malposition of one or more organs. A displaced organ may not suffer of itself, but it may push some other organ out of place and cause that organ to suffer. In the quadruped the abdominal organs hang freely from the backbone, and there is no interference of one with the other. In the biped this relation is changed. One individual in five is born with the organs of a quadruped, although that does not necessarily do any harm in itself, and that is one of the points I want to emphasize.

For instance, these patients have sacro-iliac strain because they are standing out of poise; but that in itself is a cause of visceral strain. If the viscera are not hung right, it leads to a drooped posture. In one such case I saw the stomach was down in the pelvis. Then, the stomach cannot unload itself unless the patient assumes a certain posture. The transverse colon very frequently is dropped away down. There may be a loose liver or loose kidneys. In all these cases there is an absence of retroperitoneal fat. It either never was present or it was absorbed. There is no shelf for the kidney. Sewing the stomach or any other one loose organ into place does not give these patients any relief, except for a short time only. All the loose organs must be replaced and that cannot be done by suturing.

There are certain earmarks which go with these conditions, so that this class of patients is easily recognized at sight. Ptosis of the hepatic flexure of the colon is very distressing. The progress of the intestinal contents in these cases is interfered with seriously, and the result is auto-intoxication. In the work we have been carrying on almost every combination has been found—a firmly attached ascending colon, with a free descending colon, and vice versa, or any part of the colon may be free or attached. The fluid part of the intestinal content is absorbed, and the waste is worked together into a bolus which refuses to pass onward. A patient may have a regular bowel movement and yet in the pockets and pouches formed in the walls of the colon there may be fecal matter so firmly caked that a blunt dissector is necessary to loosen it.

The Roentgen ray is of the greatest value in diagnosticating these conditions; in fact, the diagnosis cannot be made without it. You cannot relieve these patients until you get the viscera to work right. With proper treatment you can replace these organs and the Roentgen ray will aid in checking up the results of the treatment. These patients must be nourished until you can see the retroperitoneal fat. Exercises must be prescribed. The organs cannot be replaced when the chest is narrow or the body is stooped. You must make it possible to have the ribs flare so that the organs can stay in place. The posture is the result of the ptosis. When the ribs slant inward and downward, the liver and stomach are pushed out of place, which in turn interferes with the position of the colon and other viscera. That is an acquired condition. These patients must be fed properly, live properly, exercise, and observe certain rules of posture.

DISCUSSION

DR. PERCY BROWN, Boston: This opens up an interesting field of work. Hertz, of England, wrote an admirable book on constipation. He calls the conditions in the colon described by Dr. Goldthwait a hyperperistalsis, where apparently the succus entericus is formed in increased amount; everything is ready for the waste, but none comes. The so-called "greedy gut," of Hertz is an excessive contraction of the circular muscle fibers of the intestine. When the food finally comes, it is dry and the constriction of these circular fibers squeezes the food and it becomes sapless, hard and scybalous. Dr. Goldthwait's investigations are of the greatest value in directing attention to the probable cause of these conditions and their treatment.

DR. GEORGE E. PFAHLER, Philadelphia: Jordan recently called attention to a kink in the duodenum at its junction with the jejunum which may give rise to a spasmodic condition of the bowel leading to pain, ulcers, and sometimes to adhesions. This condition is easily overlooked, therefore we must make a series of examinations and do considerable fluoroscopic work. I have seen adhesious between the descending and transverse colons and sigmoid cause pain. Sometimes these patients are operated on for appendicitis, and then they fail to get relief from their symptoms. It is a problem just what to do in these cases.

DR. CHARLES L. LEONARD, Philadelphia: In one of these obscure cases I found adhesions and a stricture of the ileum which had caused the patient much pain, and which one surgeon had diagnosed as appendicitis.

DR. F. H. BALTJER, Baltimore: In two cases which I saw the abdominal viscera were in the pelvis, although the splenic flexure was held firmly in its normal position.

DR. C. E. COON, Syracuse, N. Y.: If one can show that there is a retention of the intestinal contents due to malposition of the abdominal viscera, many of these chronic sufferers will be able to get relief.

DR. ROLAND HAMMOND, Providence, R. I.: I have observed many times that while we may not change the position of the viscera by supportive and stimulative treatment, we often relieve the patient of symptoms by simply taking off the strain—the sag. By restoring the normal physiology of an organ by supportive apparatus and stimulating exercises, we are doing all that can be done and practically are effecting a cure.

DR. J. E. GOLDTHWAIT, Boston: In studying these cases we must use our good sense and not see only the colon or stomach, but the human being, with a lot of organs whose balance must be worked out. I believe that we can help these patients. These are human problems, capable of solution by human intelligence, otherwise the scheme of the universe is wrong—and it is not wrong. We cannot give these patients normal ligaments, but we can give them normal function. If we operate to replace an organ, the patient will feel better for a while, and then get much worse again, as food is taken. If there is a special condition for which suture is desirable, all right, but it must be followed up by other treatment. The same is true of the operations done for drainage of the bowel. The short circuiting of the bowel which Lane and others are doing is faulty, in that they see only the colon, and not the other abdominal viscera. It is not only the colon which is causing the mischief. You cannot do very much for the acquired cases. As for the congenital cases, if you will make the patients suffering from acquired conditions as nearly normal as possible, you will gradually lessen the number of congenital cases. It is simply a question of race improvement. If you can get these organs to work right, the patient will get well. Feed your patients judiciously and well; exercise them; train them; teach them how to stand correctly; improve their posture, and you will get good results.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

ARKANSAS: Regular, Little Rock, November 14. Sec., Dr. F. T. Murphy, Brinkley; Homeopathic, Little Rock, November 14. Sec., Dr. P. C. Williams, Texarkana.

CONNECTICUT: Regular, City Hall, New Haven, November 14. Sec., Dr. Charles A. Tuttle, 196 York Street; Homeopathic, Grace Hospital, New Haven, November 14. Sec., Dr. Edwin C. M. Hall, New Haven; Eclectic, Hotel Garde, New Haven, November 14. Sec., Dr. Thomas S. Hodge, 19 Main Street, Torrington.

ILLINOIS: Coliseum Annex, Chicago, October 26-28. Sec., Dr. J. A. Egan, Springfield.

FLORIDA: Regular, Jacksonville, November 7-8. Sec., Dr. J. D. Fernandez.

LOUISIANA: Homeopathic, New Orleans, November 13. Sec., Dr. J. T. Crebbin, 1207 Maison Blanche Building.

MAINE: City Council Rooms, Portland, November 14-15. Sec., Dr. F. W. Searle, 776 Congress Street.

NEVADA: Carson City, November 6. Sec., Dr. S. L. Lee.

TEXAS: Forth Worth, November 28. Sec., Dr. J. D. Mitchell.

WEST VIRGINIA: Hotel Waldo, Clarksburg, November 13-15. Sec., Dr. H. A. Barbee, Point Pleasant.

Texas June Report

Dr. J. D. Mitchell, secretary of the Texas State Board of Medical Examiners, reports the written examination held at Austin, June 27-29, 1911. The number of subjects examined in was 12; total number of questions asked, 120; percentage required to pass, 75. The total number of candidates examined was 148, of whom 133 passed, including 4 osteopaths, and 15 failed. The following colleges were represented:

Massachusetts July Report

Dr. Edwin B. Harvey, secretary of the Massachusetts Board of Registration in Medicine, reports the written examination held at the State House, Boston, July 11-13, 1911. The number of subjects examined in was 13; total number of questions asked, 70; percentage required to pass, 75. The total number of candidates examined was 147, of whom 94 passed, including 11 osteopaths and 2 non-graduates, and 53 failed, including 14 osteopaths and 11 non-graduates. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
[illegible]ity	(1911)	81.5
[illegible]y College	(1910)	75
[illegible] (1909) 76.2;	(1911)	75, 76, 77, 80.9
Baltimore University	(1906)	75.7
Maryland Medical College (1906) 75;	(1910)	75
Tufts College Medical School (1910) 75; (1911) 75, 75, 75, 75, 75, 75, 75, 75.2, 75.3, 76, 76.4, 77.6, 77.9, 78, 78.5, 78.5, 78.7, 79.3, 80, 80.1, 80.5, 81, 87.7.		
Harvard Medical School (1909) 76.7, 78.2, 78.3, 79.8; (1910) 77.9, 78.4; (1911) 75, 75, 75.1, 75.2, 75.8, 76.2, 76.2, 77.2, 77.2, 77.2, 77.5, 77.5, 77.7, 77.7, 77.8, 78.3, 78.4, 78.6, 79.9, 80.2, 80.5, 81, 81.5.		
Boston University (1911) 75, 75, 75, 76.2, 76.6, 77.5, 78.2, 78.4, 78.7, 81.

* A statement from the college says this candidate did not graduate.

Utah July Report

Dr. G. F. Harding, secretary of the Utah State Board of Medical Examiners, reports the written examination held at Salt Lake City, July 5-6, 1911. The number of subjects examined in was 22; percentage required to pass, 75. The total number of candidates examined was 5, all of whom passed. Eight candidates were licensed through reciprocity. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Northwestern University Medical School	(1911)	86.4, 88.4
College of Physicians and Surgeons, Chicago	(1911)	82.8
Keokuk Medical Coll. of Phys. and Surgs.	(1905)	79.3
College of Physicians and Surgeons, Baltimore	(1911)	85.5

LICENSED THROUGH RECIPROCITY

College	Year Grad.	Reciprocity with
Chi. Coll. of Med. and Surg. (1908) Colorado;	(1910)	Illinois
Illinois Medical College	(1909)	Illinois
State University of Iowa, College of Medicine	(1903)	Iowa

California August Report

Dr. Charles L. Tisdale, secretary of the California State Board of Medical Examiners, reports the written examination held at San Francisco, August 1-4, 1911. The number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 163, of whom 127 passed, including 23 osteopaths, and 36 failed, including 15 osteopaths and 1 chiropractic. Two other candidates were licensed on the basis of honorable discharge from the U. S. Services. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
University of California (1911) 78.9, 82.1, 85.1, 85.2, 85.8, 85.8, 86.5, 86.9, 90.4.

Book Notices

REPORT OF THE VICE COMMISSION OF MINNEAPOLIS TO HIS HONOR, JAMES C. HAYNES, MAYOR. Paper. Pp. 134. 1911.

This report, while not so exhaustive as the report of the Chicago Vice Commission, is yet a valuable contribution to the study of the vexing question of the regulation of vice in our large cities. The fact that Minneapolis under the present city administration is making a sincere effort to enforce the law and to do away with semi-official police regulation of vice, adds to the interest of this report. Quotations from letters from mayors, chiefs of police and others in American and European cities, appear throughout the report. The recommendation of the commission includes suggestions on law enforcement, increased police vigilance, cooperation of citizens, regulation of hotels, lodging-houses, etc. Of special interest are the recommendations, contained in paragraph V of the final sections of the report, in the interests of public health and safety. After recommending the establishment of hospital facilities for the treatment of specific cases, the commission recommends cooperation with the Hennepin County Medical Society and a careful study of the laws in various European nations and in other states, on such subjects as physical examination as a prerequisite to marriage, reporting of specific diseases, punishment for the wilful and negligent transmission of such diseases, compulsory methods for the prevention of infant blindness, and most important, the broadening of the medical practice acts so that the state board of medical examiners shall be given sufficient power and funds to control the quacks specializing in specific diseases. As only three of the fifteen members are physicians, and as the commission includes all professions and classes, this recommendation is particularly significant of the public realization of the importance of the work of the state board of examiners. This report cannot be overlooked by any one interested in the important question of vice regulation in our large cities.

DIGEST AND COMMENTS ON THE PHARMACOPEIA OF THE UNITED STATES OF AMERICA (EIGHTH DECENNIAL REVISION) AND THE NATIONAL FORMULARY (THIRD EDITION) FOR THE CALENDAR YEAR ENDING DEC. 31, 1908. By Murray Galt Motter and Martin I. Wilbert. Hyg. Lab. Bull. 75, U. S. P. H. and M.-H. S., Treasury Department, April, 1911. Paper. Pp. 564. Washington: Government Printing Office, 1911.

This bulletin is the fourth of the series and represents a comprehensive review of medical and pharmaceutic literature for the year 1908. While of interest primarily as a reflection of the work done in connection with pharmacopeial revision, these bulletins also serve to indicate the nature and kind of remedies that are being actively discussed by physicians in different parts of the world. It would appear, therefore, that to the physician who is desirous of securing reliable information regarding the remedies he is using, this bulletin will prove to be a mine of information. Not the least interesting of the several truths that are evidenced is the fact that the really active and efficient drugs are universally used not alone by regular practitioners but also by the followers of sectarian teachings or "pathies." On the other hand, it is evident that the literature relating to the use of many of the less well-established drugs is based on observations that are so unreliable, or at least questionable, that the mockery of their continuance as official articles must be apparent to every well-trained medical man.

EDUCATION AND PREVENTIVE MEDICINE. By N. E. Ditman, Ph.D., M.D. Paper. Price, 25 cents. Pp. 73. New York: Lemcke & Buechner, 1911.

"Great as has been the progress of civilization since the early centuries, there is no advance which compares in its influence on the happiness of mankind with the increased power to lessen physical suffering from disease and accident and to control the spread of pestilence." These are the opening words of this essay, originally printed in the *Columbia University Quarterly* for June, 1908, and now reprinted on account of the demand following an exhausted first edition. This is one of the best of many recent contributions on this subject, and the reprint, undoubtedly, will receive a wide circulation. Many charts and diagrams illustrate the text and a well-selected bibliography appears in the appendix.

DIE RÖNTGENSTRAHLEN IN DER GYNÄKOLOGIE MIT EINEM AUSBLICK AUF IHREN KÜNFTIGEN WERT FÜR SOZIALE UND SEXUELLE FRAGEN. Von Dr. Manfred Fraenkel, Charlottenburg. Paper. Price, 7.50 marks. Pp. 255, with 46 illustrations. Berlin: Richard Schoetz, Wilhelmstrasse 10, 1911.

This book contains a complete consideration of the subject of *x*-ray application in obstetrics and gynecology. The work is not only carefully elaborated with respect to every phase of the theme, but also includes a bibliography of the German and French literature. The study begins with a description of animal experimentation, especial reference being given to the atrophic influence of the rays on the ovary. The author then takes up what he considers a rational use of the Roentgen ray in gynecology, applying it with favorable results in such conditions as myomata, menorrhagia and metrorrhagia, dysmenorrhea and associated nervous conditions and endometritis of the hemorrhagic type. Application of the ray in carcinoma is discussed at length in a separate chapter, wherein the author claims certain rather indefinite advantages, particularly in the inoperable type.

The technic of application is described in detail, with abundant illustrations, Fraenkel placing much stress on the method of application as essential to securing desirable results.

In the use of the ray in pregnancy the danger of abortion is carefully pointed out. This is thought to be due to the influence of the rays on the syncytial elements of the placenta whereby this cell structure is destroyed or inhibited in its growth with a resultant separation. The danger of such a change is not, however, so great as has been claimed by certain investigators. The value of the ray in differential diagnosis, in differentiating uterine from extra-uterine pregnancy, in revealing twin pregnancy, etc., is brought out in detail. Fraenkel asserts also that "Roentgen examination" is of definite use in determining the probability of eventual complications where pregnancy coexists with tumors.

A TEXT-BOOK OF CHEMISTRY. For Students and Practitioners of Medicine, Pharmacy and Dentistry. By Edward Curtis Hill, M.S., M.D., Medical Analyst and Microscopist. Second Edition. Cloth. Price, $3.25 Pp. 659, with 114 illustrations. Philadelphia: F. A. Davis Co., 1911.

This is the second edition of this text and covers the same ground, but a little more fully, than the first edition. The scope of the book may best be understood from the parts into which the author has divided the material, viz.: "Medical Physics," "Chemical Philosophy," "Inorganic Chemistry," "The Carbon Compounds," "Analysis," "Incompatibility," "Sanitary Chemistry," "Toxicology," "Physiologic and Pathologic Chemistry," and "Clinical Chemistry." The text is intended for students and practitioners of medicines, pharmacy and dentistry, and is arranged and written with that end in view. None of the subjects taken up is considered in great detail, but all are covered so as to give a smattering of the various subjects, corresponding to the brief courses in chemistry given in many medical, dental and even pharmaceutical schools. The appearance in this edition of a chapter on the composition of proprietary remedies is commendable. Next to knowing the fundamentals of chemistry, the knowledge of the chemical composition of medicinal preparations is essential alike to physician, pharmacist and dentist to a scientific or rational pursuance of their several professions.

REMINISCENSES OF LINDA RICHARDS, AMERICA'S FIRST TRAINED NURSE Cloth. Price, $1 net. Pp. 121. Boston: Whitcomb & Barrows, 1911.

In this little book Miss Richards gives an account of the early days of trained nursing in this country and the establishment of training schools for nurses in connection with general hospitals, especially in New England, and the hospitals of Boston. Miss Richards' experiences have been varied, and she describes them in an interesting way. Especially fascinating is her story of her work in a missionary hospital in Japan. The training school which she organized there was at first under the control of the medical missionaries but later passed entirely into Japanese hands. Its graduates, she states, practically organized the Japanese Red Cross, and did good service in the Russo-Japanese war. The book should be of interest not only to nurses but also to physicians, especially those interested in hospital management.

Medicolegal

Constitutionality of Laws Prohibiting Discharge of Sewage Into Streams

(Town of Shelby vs. Cleveland Mill and Power Co. (N. C.), 71 S. E. R. 218)

The Supreme Court of North Carolina says that the defendant contended, as a matter of law, that it could not be restrained from emptying its raw sewage into the river some miles above the intake of the town's waterworks system, because that, prior to the enactment of the statute forbidding it, it had acquired what is called a prescriptive right to do so; that is, had a right acquired by over twenty years' continuous usage, and that consequently the statute, if it was ever intended to apply to such a case, was void to the extent that it undertook to deprive the defendant of a valuable property right without making compensation therefor.

There are authorities to the effect that, as against a private individual lower down on the stream, the right to pollute it to a greater extent than is permissible at common law may be acquired by prescription (long usage) by an upper riparian owner. But the right which the state was seeking to enforce through the statute in question was a public right—a right to protect the health of the people of the state. As against such public rights, prescription cannot run. There is no such thing as a prescriptive right to maintain a public nuisance. It followed that the defendant could not acquire any right by prescription, or otherwise, which would prevent the general assembly of the state, at any time, from exercising its police power to regulate the discharge of sewage into the river.

The issue attempted to be raised by the pleadings that the stream was not dangerously polluted by the raw sewage poured into it from a large mill settlement, working hundreds of operatives, could be of no avail to the defendant. That was a matter for the judgment of the legislature. Such legislation is preventive, and to limit it to cases in which actual injury is shown to have occurred would be to deprive it of its most effective force. To be of value, such laws must be able to restrain acts which have a tendency to produce public injury.

The second proposition of the defendant, that the right to drain its raw sewage into the river could not be taken from it without compensation, necessarily fell with the first. As the defendant could acquire no vested right of the character claimed, there was no taking of property for a public use, and nothing to compensate the defendant for. The state took no right from the defendant, but only described the conditions on which it might use the river for its private purposes.

Notice to Physician Not Notice to Company

(Lumpkin vs. Louisville & Nashville Railroad Co. (Ga.), 70 S. E. R. 1101)

The Supreme Court of Georgia holds that the mere allegation of notice to a physician, employed by a railroad company to treat injured persons, of the filing of a suit for damages, would not alone suffice to show notice to the company; it not appearing that dealing with litigation, or settlements, or the receipt of such notice, was a matter within the scope of the physician's employment. Moreover, special allegations of the petition in this case, by which it was sought to charge that the physician was the agent of the railroad company, whose knowledge would affect the company with notice, were not sufficient for that purpose.

City and Not State Must Bear Expenses of Quarantine

(City of Geneva vs. State (N. Y.), 128 N. Y. S. 570)

The Court of Claims of New York holds that, a theatrical troupe containing a case of small-pox having come to the city, the state department of health having been notified and the secretary of the State Board of Health having advised vaccination and keeping all exposed persons under strict observation until it proved successful, and a medical officer of the board having visited the city and advised quarantine, which was done, that did not make out a case of liability against the state. The city did only what was its bounden duty to do in the premises. It acted as much for its own preservation as for the state's welfare. The statute makes no provision for reimbursement, and the state officials did not even promise to repay. The claim should be dismissed.

Under the public health law, it was the legal duty of the local municipal board of health to report any case of small-pox within the municipality to the State Board of Health. It was also the duty of the municipality to guard against and prevent the introduction of any infectious disease, to enforce the isolation of all persons infected with it or exposed to it, and to provide suitable places for the quarantine and the care and treatment of such persons, and it was provided that these expenses so incurred by the local board of health should be a charge on the municipality. There is no provision in the statute for the reimbursement by the state of individuals or a locality for services rendered or expenses incurred, even under the direction of the State Board of Health.

Increase of Damages by Narcotics Prescribed in Injury Case

(Sumner vs. Kinney (Tex.), 136 S. W. R. 1192)

The Court of Civil Appeals of Texas affirms a judgment for the plaintiff, who brought the action to recover damages for wrongful assault, alleging his injuries to have been serious and that he suffered such pain that he had been obliged to resort to the use of opiates in order to obtain relief therefrom. The evidence showed that the narcotics given were necessary or proper to alleviate existing pain, in accordance with medical direction. The court holds that there was no error in a refusal to instruct the jury that if the plaintiff suffered physical pain and mental anguish, and was compelled to pay out money for medical treatment and the same was the result of the plaintiff's taking to excess narcotics, under the prescription of his medical adviser, or any person, then he would not be entitled to recover anything for the physical pain, mental anguish, and medical treatment, even though the defendant committed an unlawful assault and battery on him. The court says that it is of the opinion that what is done to an injured person in the way of proper medical treatment, applicable to him in his injured state, is attributable to the act causing the injury, as a proximate result thereof.

Good-Will Rights Attach to Practice of Medicine

(Maxwell vs. Sherman (Ala.), 55 So. R. 520)

The Supreme Court of Alabama holds that damages are recoverable for a breach of contract for the sale of the practice and good will of a practicing physician. The court says that while there has been some doubt expressed as to whether the matter of good will, as a property asset, can be applied to the practice of a physician, or other professional man, yet the weight of authority is that the good will of a physician or other professional man is a property asset, subject to disposal, within the limits prescribed, and in the same manner as the good will of any other business, and a breach of the same incurs the same liabilities.

Duty of Carriers to Women Passengers During Menstrual Periods and as to Waiting Rooms—Physical Examinations Cannot be Required

(Brackett vs. Southern Railway Co. (S. C.), 70 S. E. R. 1026)

The Supreme Court of South Carolina affirms a judgment for $200 damages in favor of the plaintiff for exposure during her menstrual period to cold in an unheated waiting-room which resulted in alleged serious and permanent sickness. The court says that it cannot accept the view that the presence of a woman's menstrual period is an abnormal condition, like weakness due to disease, of which the defendant was entitled to special notice. On the contrary, that condition is normal, and must be so regarded and taken notice of by carriers whose duty it is to provide reasonable accommodations for passengers of both sexes. That duty does not extend to making special provision, without notice, for women who are peculiarly delicate or abnormal in their susceptibility to cold in such condition, but it does extend to reasonable consideration and provision for the comfort of healthy women, whose capacity to travel is not materially affected by such condition.

Again, the court says that the public business of carrying passengers is now so controlled by a few persons or corporations that those who travel must of necessity use their stations and waiting-rooms, and with increasing population the number of persons using these stations is constantly on the increase. The arrangement for the comfort and health of all classes of the general public—women and children, the old and the feeble, the ignorant and inexperienced—are under the exclusive control of the carriers, and it seems but reasonable that they should be held to a very high degree of care in providing at their stations for the safety and comfort of those whom they impliedly invite to use their stations and waiting-rooms.

It was not error for the trial court to refuse to require the plaintiff to submit to a physical examination by disinterested physicians.

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

Yale Medical Journal, New Haven

June, XVIII, No. 1, pp. 1-112

1 Salvarsan in Syphilis. C. S. Stern, Hartford, Conn.
2 *Acute Pyelitis in Infants. W. G. Murphy, Hartford.
3 Treatment of Brain Injuries Associated with Fracture of Base of Skull. P. Watermann, Hartford.
4 *Case of Dermatomyositis. G. Blumer, New Haven.
5 Case of Metastatic Ophthalmitis in Puerperal Sepsis. E. M. Blake.

2. **Pyelitis in Infants.**—The prognosis of pyelitis, Murphy says, depends on the cause of the infection and the time it has continued. In uncomplicated cases the results are generally good. If secondary changes in the kidney have occurred the results are unfavorable. Much depends on the early recognition of the disease.

4. **Case of Dermatomyositis.**—Two years ago Blumer's patient had a mild attack of diphtheria. Two weeks after recovery from the diphtheria she had an attack of jaundice, and in the next few months seven attacks of tonsillitis. After one of the attacks of tonsillitis she had an attack similar to the present one, but confined to the legs below the knees. She had muscle pain, superficial edema and a hemorrhagic eruption over the affected parts. There was swelling of the small joints of the hands with this attack. The present illness is of two months' duration. She first had a bad attack of tonsillitis affecting both tonsils. There was no suppuration and she had home treatment. Soon after recovery she developed soreness of the muscles of the legs so that she was unable to walk. There was marked edema of the overlying skin, and many purpuric spots. Later the arms were similarly involved, and still later the face. There were spots like hives on the arms. There was no fever or at most slight fever at the onset. The face at the onset and long before edema appeared was intensely red for a day or two. Anorexia and constipation were present. When seen the main complaint was the soreness in the muscles and the swelling of the body.

This patient presented the cardinal features of dermatomyositis, pain in the muscles associated with induration and tenderness, edema of the overlying skin and dermatitis on the face in the form of a transient erythema, and on the legs as petechiæ. Points of interest in connection with the case are the following: 1. The family and personal history of asthma and other conditions suggesting hypersusceptibility to horse serum. Meltzer considers asthma a phenomenon of anaphylaxis. What relation may have existed between hypersusceptibility and the dermatomyositis is conjectural. 2. The recurrence of the disease, if the history is to be relied on. Apparently there was a mild attack limited to the legs before the more severe one. 3. The occurrence of both attacks after tonsillitis. In a good many instances this disease has followed infections.

20. **Frequency of Venereal Diseases.**—In the present organization of our hospital system in this country the notoriously inadequate provisions made for the reception and treatment of venereal patients are held by Morrow to be a disgrace to our civilization. He says that it is recognized by those who are engaged in the campaign for the prevention of venereal diseases that curative treatment, by sterilizing sources of contagion, constitutes one of the most effective measures of prophylaxis. Prompt curative treatment is not only in the interest of the patients themselves, but especially in the interest of others they might infect. But everywhere we are confronted with this situation: there are no special hospitals for this class of diseases; few general hospitals receive them in the early, curable stage; still fewer have special venereal wards; even the dispensary services are not organized with special adaptation to the needs of venereal cases; few have night classes, and working people who go to the dispensary must lose half a day, which often means the sacrifice of their employment. As a consequence, they resort to quacks or the use of nostrums, they are not cured, but go on spreading the seeds of contagion.

Our hospital authorities are most loyal advocates of the policy of silence and concealment which has always served to cover up the enormous extent and dangers of venereal infection. By the system of nomenclature employed in the records all mention of gonorrhea and syphilis is excluded in thousands of cases indubitably of venereal origin, or presumptively so. It would be impossible for a physician, much less a layman, to obtain any correct idea of the amount of venereal morbidity in a general hospital from the examination of its records. It is only in the hospital records of the Army and Navy departments that gonorrhea and syphilis are always entered under their true names. As regards the venereal peril in our civil population, Morrow says that venereal diseases, viewed in their triple significance as a danger to the public health, a peril to the family, and a menace to the vitality, health and physical progress of the race, are the greatest of modern plagues, and that the prophylaxis of these diseases is the most pressing problem of preventive medicine that confronts us at the present day.

36 *Method for Quantitative Determination of Bacteria in Feces. H. A. Mattill and P. B. Hawk, Urbana.

32. **Experimental Acute Nephritis.**—The authors found that uranium and cantharidin, in the smallest doses capable of producing a distinct nephritis, tend to increase the elimination of nitrogen, probably by stimulating tissue katabolism. Uranium, cantharidin, and potassium chromate, in larger doses, impair the power of the kidney to eliminate nitrogen; but this may not be evident unless the animal is on a high nitrogen diet, and the impairment, when due to potassium chromate, may not persist more than a day. Small doses of uranium and of cantharidin cause a transient increase of chlorid elimination which corresponds in a general way to the excess of diuresis. Large doses of uranium and of chromate cause a fall, usually transient, in the chlorid elimination. The chlorid elimination may, however, be diminished 40 per cent. for twenty-four hours without evidences of intoxication (vomiting). The anatomic appearance of the kidney varies somewhat with the poison used and greatly with the period of survival after administration of the poison, but bears no definite relation to the nitrogen, chlorid or phenolsulphonephthalein elimination; marked anatomic alteration is compatible with normal elimination of all these substances and with freedom from symptoms of intoxication (vomiting).

The decrease in the elimination of phenolsulphonephthalein, which occurs in uranium, chromate and cantharidin nephritides and which, in a general way, is proportional to the dose of the poison, bears no constant relation to the changes in the nitrogen or chlorid elimination. A marked decrease in the elimination of the phenolsulphonephthalein occurs synchronously, as a rule, with the onset of the symptoms of intoxication (vomiting), and therefore the phenolsulphonephthalein test would seem to be a better indicator of the ability of the kidney to eliminate the toxic substance responsible for the symptoms of renal insufficiency than are either the anatomic changes or the elimination of total nitrogen or of chlorids.

33. **Biologic Tests for Adrenalin in Blood.**—The combination of a biologic test object on which adrenalin causes contraction of smooth muscle (perfused blood-vessels or the uterus in certain conditions) with a biologic test object on which it produces inhibition of contraction of smooth muscle (intestine) Stewart says greatly diminishes the chance of error in testing blood (or other body liquids) for adrenalin. A control experiment with adrenalin solutions should, in general, accompany each observation on the blood. When properly chosen biologic tests are employed, no evidence is obtained of the presence of adrenalin in detectable amount in normal blood taken from the general circulation. In a case of nephritis with albuminuria and persistently high arterial pressure, the pressure was diminished by forced breathing. The washing out of carbon dioxid seemed to be a factor in this diminution as well as the mechanical interference with the circulation. In this case, the administration of large doses of sodium bicarbonate was associated with a marked diminution in the blood-pressure. In another case with persistently high blood-pressure, the drawing off of cerebrospinal fluid caused a distinct diminution in the arterial pressure, presumably by lowering the intracranial pressure. No pressor substance was detected in the cerebrospinal fluid.

34. **Biliary Cirrhosis in Rabbit.**—The statement concerning biliary cirrhosis which is commonly found in text-books on pathology is to the effect that obstruction of the bile duct without infection does not lead to cirrhosis of the liver. Richardson found, however, that ligation of the common bile-duct in the rabbit, without demonstrable succeeding infection, results in a cirrhosis of the liver.

35. **Relation of Optic Thalamus to Respiration.**—Sachs failed to find a center controlling respiration in the optic thalamus. He says that any changes in respiration observed on stimulation are reflex effects. The blood-pressure is not governed by any special center in the thalamus; the changes observed are, as a rule, pressor effects. Changes in pulse-rate do not occur from moderate thalmic excitation. There is no center controlling movements of the spleen; all changes are secondary to blood-pressure changes. The difference in respiratory effects noted on the stimulation of the thalamus and central gray matter are in all probability due to the stimulation of different paths going to the medullary centers. The globus pallidus has an entirely different effect on the respiration from the thalamus and hence is connected with a different part of the medullary center. The nucleus caudatus has no connection with the respiratory or circulatory mechanism. The optic thalamus, nucleus caudatus, and nucleus lenticularis contain no centers which on direct stimulation produce changes in temperature.

36. **Quantitative Determination of Fecal Bacteria.**—From results obtained by Mattill and Hawk it appears that the amount of bacterial nitrogen in the feces is a valuable index to intestinal conditions, and the method described by them is a simple and satisfactory one for making this determination. It involves three serial centrifugalizations of a 2 gm. sample of the fresh feces brought into suspension in 0.2 per cent. hydrochloric acid. The bacterial suspension finally obtained is concentrated and extracted by alcohol, and nitrogen is determined in the precipitated material. The complete data on a given stool can be obtained in about five days, and one operator can take care of three or four stools in duplicate in one day. On an absolutely uniform diet of simple and easily digested food during a period of three to four weeks, the average amount of bacterial nitrogen in two subjects was found to be 53.9 per cent. of the total fecal nitrogen, and this percentage, though higher than that obtained by workers heretofore, is probably more nearly a true value for bacterial nitrogen, because no ether extraction was employed. The average daily amount of dry bacteria, calculated on the basis of the nitrogen values, is 8.27 Gm.

40. **Empyema of Gall-Bladder.**—Bobb does not believe that it is not necessary, as a rule, to remove the gall-bladder in these cases of empyema; drainage, if the mucosa is not all destroyed, being sufficient. He regards all cases of empyema of the gall-bladder as necessarily surgical, and suggests that if more cases of simple cholecystitis were operated on it would save the larger mortality that is obvious in empyema.

43. **Symptoms Due to Unsuspected Ethmoiditis.**—According to Todd it not infrequently happens that the antrum acts as a reservoir for the pus which originates in the ethmoidal or frontal cells, and hence efforts to cure an antrum abscess, without first curing the ethmoidal or frontal sinus abscess, prove futile, while, conversely, the curing of the latter will usually result in cure of the antrum disease without any attention being directed to the antrum itself.

51. **Treatment of Pruritus.**—After all local and constitutional measures had failed to give relief to a woman, 33 years old, Cole removed the clitoris and its prepuce, part of the mons, the labia minora, part of the vestibule, and the integument from the inner aspect of the labia majora. On examination the inner surfaces of the labia majora were found to be whitish in character and the epidermis very much thickened, the labia minora not prominent, and the clitoris was almost completely concealed beneath the prepucial tissues, which were white, indurated and very much thickened. Further from the center of involvement the surface had a reddish, shiny appearance, and some small ulcerative areas were present, with marked manifestation of undue manipulation of the parts excited by unbearable itching. The symptoms were immediately relieved. The wound healed by primary union. Four months have elapsed, with no return of symptoms, and the patient feels much elated with her condition.

55. **Acute Poliomyelitis in Pennsylvania.**—Out of 773 cases of poliomyelitis studied carefully by the department of health of the state of Pennsylvania, fifty-nine gave a distinct history of exposure to previous cases. Nationality seemed to play no particular part in this disease, the vast majority of those contracting poliomyelitis being American-born. Out of this series of cases 437 were males and 336 were females. But three of the colored race (two males and one female) sickened. In forty-four instances secondary cases developed in the household. Other acute illnesses two months prior to the development of infantile paralysis seemed to show but little influence. Great exposure to heat, cold and dampness was noted in comparatively few instances. A total of thirty patients are reported to have met with some minor accident a short time previous to the onset of poliomyelitis. Overexertion was reported in only twenty-eight cases. In a few instances (thirty-four) evidence of insect bites was noted.

In this series of 733 cases, 142 patients (18.4 per cent.) recovered without paralysis and 294 (71.6 per cent.) recovered with considerable residual paralysis. Housing conditions show that in 149 instances the individual sickened in a large home; in 219 instances in a medium-sized home, and in 164 instances in a small dwelling. When classified with reference to the number of members of the household the tabulation shows two instances in a family of one; thirteen in a family of two; eighty-six in a family of three; 154 in a family of four; 121 in a family of five; ninety-five in a family of six; sixty-two in a family of seven; thirty-three in a family of eight; twenty-three in a family of nine; twenty-three in a family of ten and over. These figures establish the fact that the danger of transmission from one member of the household to another member of the same household is not great. In 289 instances children slept in the same bed-room, only twenty-four contracted the disease.

In nine instances the disease developed in children after having visited communities where this disease was known to be prevalent. In five cases the possibility of transmission through a second individual seemed probable. In many histories rats were reported on the premises. Field mice were frequently found. Unusual insects were reported in eighteen instances.

In examining the blood from acute cases of poliomyelitis in human beings, and also in monkeys in which the disease was produced experimentally, an organism was found different in morphologic characteristics from any heretofore described. Blood-smears being fixed in methyl alcohol for one minute and stained with carbol-thionin, show the organism as a faintly-stained blue rod with regular cell wall about 10 microns long and about 8 microns in width, curved at an angle of 60 to 75 degrees at one end, occasionally at both ends. At times, the curved end is bulbous. Some of the organisms appear to have a very finely granular protoplasm when the highest amplification is employed. They may be discerned by means of a 4 mm. dry objective but their characteristics are much more satisfactorily delineated under the 1/12 oil-immersion lens. They are found free in the serum as well as within the body of the red blood-cell. The organisms do not retain the violet color when stained by the method of Gram but assume the color of the counter stain which, as generally used in this laboratory, is a very dilute solution of carbol-fuchsin.

The bloods examined were from ten different cases of acute poliomyelitis in children, and from thirteen cases of the disease during the acute stage, which had been produced experimentally in as many monkeys. Blood-smears from three normal human beings were carefully examined and although the search for these organisms was diligently made, none was found. Smears were made from the blood of thirteen normal monkeys with negative results. After inoculation with the virus these same monkeys gave positive results. The blood of other normal monkeys gave negative results. Blood-smears were stained with iodin and sulphuric acid in order to test the organisms for cellulose, but no blue stained organisms were seen. Smears from the cords and brains of paralyzed monkeys, and from one human case were examined, but none of the new organisms was found. Filtered virus stained with carbolthionin and by Gram's method showed none of these organisms. Defibrinated blood, three weeks to two months old, from two paralyzed monkeys, showed the forms in increased numbers. Cultures made from the blood of a paralyzed monkey, in blood bouillon, plain bouillon and blood-agar, examined after having been inoculated three weeks, showed the presence of the organism in increased numbers. Dorsett's egg medium was inoculated with the same blood at the same time but the organism was not found in smears from the surface of the medium or from the water of condensation. Experiments on the production of poliomyelitis in monkeys by using this organism are in progress.

56. **Gastric and Pancreatic Fat Digestion in Infants.**—The authors conclude that the neutralization of the fat gastric digestion does not end the function of the gastric lipase of the dog or infant. Whether the effect shown is a summation of, or a relationship between, the actions of the two ferments, preparatory or activating, their experimental results do not permit them to state with certainty. They believe it to be justifiable, however, to conclude that the function of the gastric lipase of the infant is not ended when the gastric contents pass the pylorus and are neutralized in the duodenum.

59. **Meat Ingestion and Indicanuria in Children.**—The following is a brief resumé of the results obtained by Fleischner: With an ordinary diet containing meat once daily, children 6, 9 and 12 years old succeed in digesting their food fairly well without much putrefaction in the intestinal tract. Three-year-old children, on the other hand, with the same diet are much more apt to show indicanuria. The giving of meat twice daily produces in 9- and 12-year-old children practically no change in the amount of intestinal putrefaction. In 6- and even more markedly in 3-year-old children meat given twice daily gives rise to a decided increase in the indicanuria and is a cause of pronounced intestinal putrefaction. As limited as these observations may be, they seem to point to one definite conclusion, and that is that the giving of meat more than once daily to children under 9 years of age is a practice conducive to intestinal putrefaction and indicanuria, and is to be deprecated on account of the harm resulting to the organism from the constant presence of abnormal products of putrefaction.

60. **Treatment of Chronic Nephritis in Children.**—The five cases cited by Koplik seem to have strengthened his belief in the efficacy of this operation.

68. **Neuritis Puerperalis.**—Two cases are reported by Spear. In the first case there is a history of a very probable multiple neuritis complicating a pregnancy that occurred five years ago. In this attack it is perfectly possible to exclude all forms of exogenous toxemia, trauma, infectious diseases, etc. This woman was desperately ill from her hyperemesis gravidarium, and had a typical multiple neuritis. The institution of the proper treatment for the hyperemesis gravidarium with only slight treatment directed toward the multiple neuritis resulted in a prompt and perfect recovery. In the second case the patient had all the signs and symptoms of a severe case of multiple neuritis, with marked disturbance of memory for recent events, presenting a typical picture of Korsakow's disease. From a very careful inquiry of her surroundings, habits, etc., chronic alcoholism could be excluded absolutely. Korsakow's syndrome can be caused by some other toxin than alcohol.

76 and 77. Abstracted in THE JOURNAL, June 3, 1911, p. 1676.

80. **Active Immunization in Animals.**—Complete extirpation of the pancreas must necessarily result in profound disturbances of metabolism, but it was thought by the authors that notwithstanding such disturbances a very definite relation might still be shown to exist in the diminished resistance which such a pancreatectomized animal would present to bacterial infection. Ten dogs were used in the experiments. No. 1 was used as the index of unity, for obtaining leukocytes and normal serum in the determination of the opsonic indices. Nos. 2 and 3, which were neither pancreatectomized nor inoculated, were used as normal controls. Nos. 4 and 5 were not pancreatectomized, but were inoculated; these they called controls. The remaining five dogs were pancreatectomized. The opsonic indices of all of the ten animals were determined according to Wright's method previous to and five days subsequent to the operations, and thereafter at seven-day intervals for a period of six weeks. The organism used in obtaining the indices and for the preparation of the bacterin was the same strain of *Micrococcus aureus*. In ascertaining the indices, there were counted in each case 100 leukocytes with their bacterial contents.

Five days after the opsonic indices of all animals were determined. Dog 7 died six days after the operation. One pancreatectomized dog, No. 10, was not given an inoculation, but was used as a control. One week subsequent to the operations the remaining pancreatectomized animals, Nos. 6, 8 and 9, and the two controls, Nos. 4 and 5, were inoculated with a sterilized suspension of the *Micrococcus aureus*, the dose in each case being 400,000,000 bacteria. No. 8 died five days after the inoculation, so that in this case also the authors were unable to obtain more than one index. Two more inoculations of the sterilized bacterin were given at seven-day intervals, each dose being increased by 200,000,000 and 400,000,000, respectively, and the opsonic indices determined after the time the positive phase should have been reached. Four weeks after the operations and one week subsequent to the last inoculation of the sterilized bacterin, two injections of live cocci were given in respective doses of 150,000,000 and 225,000,000 at seven-day intervals. The authors were unable to give more than two inoculations of the live organisms to the pancreatectomized animals, as they died six weeks after the operations; but the controls, Nos. 4 and 5, received seven inoculations in all, of the live becterin, at seven-day intervals, each dose being increased by 75,000,000, thus bringing the last dose up to 600,000,000. Subsequent autopsy in the operative cases proved that the entire pancreas had been removed in each one. Urine was collected and tested for sugar with positive results; tests for acetone also were positive.

They have drawn several conclusions: 1. The gradually declining indices of the pancreatectomized dogs, inoculated and non-inoculated, as contrasted with the practically even index curves of the normal controls, show a diminution in the mechanism for the production of immunity, since the index curves of the two dogs which received bacterins show no pronounced difference from that of the animal which did not. 2. A comparison of this almost regular decline with the gradual rise of the indices of the non-pancreatectomized, but inoculated, animals would seem to indicate that the production of this protective mechanism depends, at least in part, on the functional activity of the pancreas. 3. The fact that the index curve in dog 10, which was not inoculated, differs so slightly from those of the pancreatectomized and inoculated dogs would furnish an explanation, in part, of the liability of diabetics to staphylococcus infection, as evidenced by the frequency of boils and carbuncles in such cases. A study of the curves in animals 4 and 5 would seem to show that in a normal healthy animal a more pronounced immunity may be obtained by the use of a sterilized bacterin.

87. **Method of Calculating Milk Formulas.**—Starting with the belief that in practice it is unnecessary that the percentage of fat should ever be more than twice that of the protein. Holt has found it easy to construct a table by which a series of formulas can be obtained in which the fat may be as high as twice the protein, and as low as only a little more than one-fourth the protein, with all the variations between these extreme limits. The first step is to secure milks which contain different fat percentages: 7 per cent. of fat, 6 per cent., 5, 4, 3, 2 and 1 per cent. How this is done from 1 quart bottle of milk which has 4 per cent. of fat, and one which has 5 per cent. of fat is shown in the following table:

1 ounce milk sugar by weight in 20-ounce mixture adds 5 per cent.
1 ounce milk sugar by volume in 20-ounce mixture adds about 3 per cent.
1 even tablespoonful in 20-ounce mixture adds 1.75 per cent.

Every ounce of 7 per cent. milk in a 20-ounce mixture will add 1/20 of 7 per cent., or .35 per cent. of fat; every ounce of 6 per cent. milk will add .30 fat; every ounce of 5 per cent. milk will add .25 fat, etc. Every ounce of each of these milks will also carry with it .175 per cent. of protein and .225 of sugar. In the case of a young infant for whom .70 per cent. of protein is proper, 4 ounces of milk in 20 ounces of food will be required. If this 4 ounces is of 7 per cent. milk the food will have 1.40 per cent. of fat; if it is 6 per cent. milk the food will have 1.20 fat; if 5 per cent. 1.00, etc. To raise both the fat and the protein proportionally the next increase would be to use 5 ounces of 7 per cent. milk in 20 ounces of food; later 6 ounces in 20; 7 ounces in 20, etc., etc.

To raise the protein above .70 but without increasing the fat, this can be done by using 1 ounce more of milk in 20, but of the series containing the next lower fat; e. g., 5 ounces of 6 per cent.; 6 ounces of 5 per cent.; 7 ounces of 4 per cent., and 9 ounces of 3 per cent., all give approximately the same fat while the protein is raised successively from .70 to .85, 1.05, 1.20 and 1.60 per cent. In calculating the sugar percentage it is necessary only to see how much must be added to that already in the milk to bring it up to the percentage desired, remembering that:

	From 4 Per Cent. Milk.	From 5 Per Cent. Milk.
To obtain 7 per cent milk use	upper 16 oz.	upper 20 oz.
To obtain 6 per cent. milk use	upper 20 oz.	upper 24 oz.
To obtain 5 per cent. milk use	upper 24 oz.	all
To obtain 4 per cent. milk use	all	remainder after skimming off 2 oz.
To obtain 3 per cent. milk use	remainder after skimming off 2 oz.	remainder after skimming off 3 oz.
To obtain 2 per cent. milk use	remainder after skimming off 4 oz.	remainder after skimming off 5 oz.
To obtain 1 per cent. milk use	remainder after skimming off 8 oz.	remainder after skimming off 8 oz.

When more than 20 ounces of food is to be made up one should add for 25 ounces one-quarter more of each ingredient; for 30 ounces one-half more; for 40 ounces twice as much, etc. In order to calculate the caloric value of the food quickly it is only necessary to note the number of ounces of the milk used in the formula, multiply this by the caloric value of 1 ounce, and add the caloric value of the sugar or barley used in the formula.

88. Abstracted in THE JOURNAL, July 8, 1911, p. 152.

92. **Surgical Management of Acute Abscesses.**—Southworth says that in the common acute type of glandular suppuration in infancy and early childhood suppuration is not diffuse, but more or less limited by the line of the distended capsule of the gland. The infection having been rounded up and brought under control by the sacrifice of the parenchyma of the gland, Nature seeks as speedily as possible to evacuate the pus and detritus. Therefore, in incising such abscesses do not check a destructive process by heroic measures, but give just the requisite amount of aid to complete a conservative process. When this is accomplished, restitution of the surrounding tissues proceeds with the greatest rapidity.

93. **Treatment of Furunculosis in Children.**—In the past three years McDonald has treated twenty-eight cases in children varying in age from 2 months to 3 years with bacterial vaccines including those with a few scattered furuncles here and there to cases in which they were so large and numerous that it was difficult to find a spot not infected for the passage of the hypodermic needle. The staphylococcus aureus and albus were the causative organisms in all cases. The average initial dose was 25,000,000 staphylococci. Some cases received as high as 150,000,000 without untoward results. The average number of inoculations per patient were three, spaced seven days apart. In three cases there was light redness and swelling at the point of inoculation, which subsided in two or three days. It was not an uncommon occurrence for a fresh crop of furuncles, usually small in size, to appear two or three days after the first inoculation. This, however, did not follow subsequent inoculations.

104. **Bacillus Coli Infection of Urinary Tract.**—During the past two years Rawls has observed quite a number of colon bacillus infections of the urinary tract. He is convinced that in a certain percentage of adults, even in health, the *B. coli* is taken up by the lymphatics and blood-vessels of the intestines and deposited by the blood-current in the kidneys. The number and virulence of these microorganisms depend on the intestinal disturbance and the particular strain present. The greatest predisposing cause of *B. coli* infection of the urinary tract, in his opinion, is anything that interferes with a free secretion of urine or causes any back pressure in the urinary tract. The earliest symptoms of such infection of the urinary tract are apt to be mistaken for those of a mild cystitis, whereas the real site of infection is most often higher up in the urinary tract and of more serious pathologic import. With greater care in diagnosis, Rawls says, we will find that *B. coli* infections of the urinary tract are likely to be mistaken for other acute conditions, such as appendicitis, malaria, intestinal indigestion, toxemia of pregnancy, ether nephritis, and acute and chronic nephritis. This is especially true of postoperative gynecologic cases.

105. **Chronic Dysentery Non-Amebic in Nature.**—Observation of four cases has convinced Bassler that there is a chronic form of dysentery due to the *B. coli communis*, and that these cases are not uncommon in the temperate climates. The form of infecting organisms does not correspond to the Shiga or the mannite-fermenting types, and that they are not possible of differentiation from the known forms of *B. coli communis* of high virulence. The serums from Bassler's cases strongly agglutinated the organisms obtained from that person and more definitely than they did the strains of *B. coli communis* ordinarily obtained and used in laboratory observations. The organisms existed in large numbers in the lower intestinal tract of the patients, mostly in the mucus, and that they are capable of destruction of tissue locally with the production of ulcers and then living within the tissue of the gut wall in the bases of them. In the etiology of these cases Bassler says we are dealing either with a definite organism of the *B. coli* group, or with *B. coli communis* of a high virulence, strongly hemiparasitic in nature and from which the aggressin production is overwhelming and against the effects of which in susceptible individuals the body cannot resist local tissue infection.

125 *Achroodextrin Saturation Test. H. Weinstein, New York.

119. **Cancer of Stomach.**—Erdmann has done fourteen partial gastrectomies with pylorectomies during the past two years. Of these, one was for a marked induration with ulcer, one in a case accompanied by transverse colectomy, and another in which a removal of the greater portion of the transverse colon was necessitated by injury to the colica media. The others were typical operations of this class. The ages varied from 28 years in a male, with infiltrating carcinoma implanted on a saddle ulcer, to 68 years, in a male in whom the entire transverse colon was removed. In addition to these fourteen he has done a partial gastrectomy with plastic repair in a male for sarcoma of the greater curvature. Of the fourteen gastrectomies the two complicated with colectomy ended fatally, and two of the typical excisions were also fatal, giving a mortality in the typical, noncomplicated cases of three deaths out of thirteen, including the one of injury to the transverse colon as a typical one or 23 per cent. One of the patients in the typical cases did very well until his seventh day, when he refused food, practically starving to death. The other death was due to taking an undue hemoglobin risk, the percentage being well below forty. Death followed in thirty-six hours.

As for the after-care: Erdmann has never hesitated to give these patients water a few hours after the operation. They are placed in the semisitting position as soon as they are in bed. After the first six to twelve hours nourishing liquids, usually albumin water or broths, are given; then milk. On the third day soft foods, and from the fifth to the seventh day creamed potatoes, spinach, and thoroughly masticated meats are allowed. In fact, the patient craves fluids and food, and these are rushed in small quantities frequently given. The patients are allowed to be out of bed about the fourth day, all things being equal, and walk about, from the seventh to the tenth days. Erdmann agrees with Rodman that, when the *stomach is exposed and a marked* induration is found even if we are satisfied that it is due to ulcer, an excision of the ulcer bearing area is the operation of choice and necessity.

125. **Achroodextrin Saturation Test.**—Summing up his clinical experience Weinstein concludes that achroodextrin and erythrodextrin are both frequently found in hyperchlorhydria, and amylodextrin may be absent. In normal secretion there may be no erythrodextrin, but small quantities of achroodextrin and a preponderance of amidulin may be found. Even in subacidity there may be no erythrodextrin, while achroodextrin and amidulin may both be present. All the dextrins may frequently be demonstrated in the filtrate, irrespective of the secretory condition, excepting anacidity. Achroodextrin and maltose are almost always present in the filtrate. From these results it would appear that some other factors, besides the state of secretion, play an important rôle in influencing the amylolytic process in the stomach. The examinations were confined solely to the aspirated stomach contents after an Ewald test breakfast. Realizing the coarseness of the test usually employed, Weinstein experimented with various dilutions of iodin until he decided on a 1 per cent. alcoholic solution of iodin as the most convenient reagent. He based his test on the property possessed by achroodextrin to absorb iodin without giving rise to a color reaction. As soon as all the achroodextrin in the solution has become saturated, the characteristic color reaction of the preponderating dextrin appears. Weinstein terms it the achroodextrin saturation test. The test is both qualitative and quantitative in character, and although the quantitative phase is not absolute it possesses some value for comparative purposes. The mode of procedure is a follows: To 5 c.c. of the filtrate the reagent is added drop by drop, all the while agitating the mixture, until a decided discoloration takes place. If the color reaction is faint, the number of drops requisite for its production constitutes the saturation index for achroodextrin; if intense, one drop below the number required for its production is to be taken as the index. The result is then computed in 100 c.c. If amylodextrin is present in the solution, the color reaction obtained is a faint blue, which deepens as the reagent is added drop by drop. If no change takes place from the violet blue color, there is no other dextrin in the solution. In the presence of erythrodextrin, however, the end reaction of amylodextrin is a mahogany brown color. In the absence of amidulin the color is reddish or brownish from the very beginning. There is then no need going any further, as this color change precludes the presence of amidulin. The quantity of erythrodextrin is in inverse ratio to the depth of color. It is of no practical advantage to determine the quantity of erythrodextrin, aside from its being extremely difficult to determine its end reaction.

1. **External Polypoid Tumors of Stomach.**—Sherren describes pedunculated growths springing from the stomach. usually originating from its posterior surface near the greater curvature. They grow into and often become intimately adherent to the lesser peritoneal sac. In a few instances they have sprung from the lesser curvature and grown between the layers of the gastrohepatic omentum. These tumors are met with more often between the ages of 35 and 55, and are more common in women. Sherren has been able to collect eighteen cases in which the sex was mentioned; thirteen were women. The characteristic feature of a case of this nature is the discovery of a tumor in the upper or mid-abdomen in a patient whose chief or only complaint is abdominal discomfort. Occasionally the presence of an abdominal swelling is the only thing noticed. The tumors are smooth and rounded, often cystic and movable from side to side. In a woman the diagnosis of an ovarian tumor is almost inevitable if the tumor is large and fills the mid and lower abdomen. Operations were undertaken with this diagnosis in several cases.

Tumors of this type have certain features in common; they are mesoblastic in origin, and usually form polypoid masses hanging from the greater curvature of the stomach into the lesser sac, to which they become adherent. Their exact nature is only discovered on microscopic examination. They are usually malignant, and may start in the submucous, muscular or serous coats, but do not involve the mucous membrane. When originating in the first and last situations they are always malignant, but tumors described as myomata may grow from the muscular coat and present no sign of malignancy. In other cases with similar microscopic characters secondary deposits have been found—leiomyoma malignum. Thus in fourteen recorded cases of operation for gastric myoma four were of this nature. Diagnosis of their exact nature is impossible before operation. Treatment should be by removal with wide resection of the gastric wall from which the tumor springs.

2. **Epidemic Summer Diarrhea and Vomiting.**—Briefly, the method employed in the East London Hospital for Children, as described by Waller and Walker, is as follows: On admission the stomach is washed out with saline (0.9 per cent. solution) at a temperature of 110 F. The gastric contents are often exceedingly foul smelling and copious. With very few exceptions the vomiting ceases absolutely and does not recur. The rectum is next washed out with saline at a similar temperature, the irrigation continuing until the return flow is clear. If done in this order time is saved, as the bowels usually move freely during the gastric lavage, and the subsequent rectal irrigation is a shorter proceeding. If any great degree of collapse or shock is present a mustard bath, or in extreme cases, a mustard pack, is given, and is one of the most useful remedies that can be employed. The child will, as a rule, then sleep quietly for an hour or so, during which time a subcutaneous infusion of normal saline, or of a 5 per cent. solution of glucose in normal saline, is started.

3. **Pleural Tuberculosis with Large Effusion.**—In the case cited by Carter, that of a man 30 years old, 9 pints and 8 ounces (188 ounces) of clear yellow fluid were withdrawn from the right side through a small cannula in twenty minutes. At the end of the time the fluid was still running, but as the patient began to cough and his pulse showed irregularity, it was considered advisable to withdraw the instrument. Tapping was soon needed again, and 90 ounces and 100 ounces were removed on separate occasions from the right side, while the left side yielded 60 ounces once. The fluid removed presented the characters of an exudate rather than a transudate. Fraenkel's pneumococcus was recovered from it, but no tubercle bacilli The latter were also absent from the scanty sputum. Later 125 ounces were removed from the right chest with some temporary improvement. Tapping the pleura toward the end yielded very small amounts of fluid (2 ounces).

4. **Tubercle Bacilli in Sputum.**—The method used by Eurich is the one originally described by Koslow in 1910. A quantity of the sputum is shaken up with a strongly alkaline sodium hypochlorite solution (15 per cent. liquor sodæ hydrasel, such as a measure cylinder, the proportions depending on tus plus liquor sodæ chlorinatus āā) in a glass-stoppered vessel, such as a measure cylinder, the proportions depending on the consistence of the sputum; if the latter is very viscid or dense an equal proportion may be required; if thin, then half the amount may suffice. The mixture is occasionally shaken during five minutes; it is then diluted with a volume of distilled water approximately ten times as great as that of the sodium hypochlorite solution used, and again shaken for a few minutes. Finally there is added a mixture of equal parts of ether (methylated ether will do) and acetone equal in volume to that of the water. It is shaken once more for a few seconds and the whole allowed to stand. In a few minutes the contents of the bottle will be found to separate into three layers. The middle layer, appearing as a more or less dense white ring, will contain nearly all the tubercle bacilli that may be present in the sputum, and can be drawn off with ease by means of a pipette fitted with a teat. The density of this middle layer can be increased after it has been pipetted off, if desired, with the help of a centrifuge (an ordinary hand centrifuge will answer the purpose), but it is not necessary. A film is made, dried and fixed in the usual way by passing it through a flame. Before staining the film Eurich immerses it for a few seconds in 5 per cent. sulphuric acid to neutralize any adhering alkali, and it is washed to remove the acid. If the examiner is interrupted, or otherwise pressed for time, the whole mixture may be allowed to stand till the next day or even longer; the acid-fast property of the bacilli is not affected by the delay. The mixture should be diluted with distilled, not with tap water, as the latter may contain acid-fast bacilli.

7. **Circulation Factors Admitting of Easy Measurement.**—The factors in circulation admitting of easy measurement and which are discussed by Haig are the capillary reflux, the blood-pressure, the ratio of capillary reflux to blood-pressure, the cardiac diameter and the liver dulness.

8. **Valves in Veins of Portal System.**—To sum up, Wilkie emphasizes that we have now definite proof that there are valves in the veins of the portal system; that these valves are widely distributed throughout the tributaries of the portal vein, and that while well developed in the infant and young child they tend to become incompetent in the adult. These valves, which are well developed in most of the lower mammals, appear in man to be undergoing a retrograde metamorphosis.

9. **Action of Ilio-Psoas Muscle.**—Evidence is given by MacLennan to prove that the ilio-psoas muscle is not an adductor, but an abductor, not an inward but an outward rotator of the femur.

15. **Nutritive Effects of Beef Extract.**—The authors' experiments tended to prove that the addition to the diet of the beef extracts used (commercial and self-made) led to an increase of body weight both in the case of animals and of man. Accompanying this increase there was a retention of a considerable proportion of the nitrogen given in the extracts. The extracts also caused a reduction in the output of nitrogen by the feces, this no doubt being due to a better digestion and absorption of food of the ordinary diet. The extracts may therefore be accredited with both a direct and an indirect nutritive value. During the feeding with the extracts there was also a retention of water in the body.

23. **Merits of Low Protein Diet.**—Reliance on protein as a source of energy is held by Chittenden to be theoretically and practically undesirable. It is true that the protein molecule contains, in addition to its 16 per cent. of nitrogen, 52 per cent. of carbon. After the molecule is denitrogenated, the residue, the non-nitrogenous moiety of Foster, can serve the same purpose in the body as fat and carbohydrate, but to obtain energy from this source means letting loose in the system a mass of nitrogenous waste products which the body cannot use and which must be eliminated at some expense, even if no other undesirable results follow. Why not, asks Chittenden, rely on fat and carbohydrate for the energy needed by the body, and use protein food solely for the purposes which it, and it alone, is especially fitted to fulfil? Such a course has the merit of being more closely in accord with physiologic laws, while at the same time there is a suggestion of conservation of health and strength, combined with a certain amount of physiologic economy, that may ultimately result in increased efficiency.

42 *Case of Hydatid of Colon. A. Honman.
43 Intrauterine Crying of Child. R. H. Fetherston.

31. **Appendicitis Due to Hydatid.**—In this case the appendix was found lying behind the cecum with an adherent mass near its tip. The mass proved to be a hydatid cyst. Spread over the cyst and along the anterior surface of the appendix were tortuous dilated veins. The cyst had developed between the layers of the meso-appendix, from which the adventitious coat had arisen. Traction of the cyst at the appendix had produced a kink at the point of attachment, and this kink had apparently caused the symptoms, for a microscopic section of this part of the appendical wall showed constriction of the lumen and engorged, dilated vessels, but no other signs of inflammation. Examination of some of the clear cyst fluid revealed typical hydatid scolices. Projecting through the serous coat of the appendix nearer the proximal end were two small white rounded bodies, probably hydatid cysts in an early stage of development.

42. **Hydatid of Colon.**—Honman's patient had had during eight months four attacks of severe abdominal pains, accompanied with vomiting. In December he had a severe attack and had vomited a quantity of blood and large quantities of bile, and had passed a quantity of blood by the bowels; this was followed by obstruction of the bowels, which was finally relieved by high enemas, etc. His condition was diagnosed as ulcer of the stomach and he was sent into a private hospital and treated by artificial feeding, etc., and he left there the following January considerably improved. On returning to work, which entailed a lot of riding, his pains returned, and on consulting Honman he stated that while he was in no pain he suffered from indigestion, had had blood in his motions to a more or less degree for the previous three weeks, and had tarry motions and complained of pain in the right groin and on urinating. There was marked rigidity of the muscles over the right side of the abdomen, and a mass could be felt rather higher than the normal appendicular region, and there was some tenderness on deep pressure there. The urine was free from albumin, pus or blood. Honman operated and found a hard mass covered with adhesions, which, on separating, showed a growth attached to the ascending colon, and as it presented every appearance of being a sarcoma, and was protruding into the lumen of the intestine, Honman resected the colon, joining by end-to-end anastomosis. The mass had a very thick wall and was closely packed with hydatid cysts; the larger pole of the growth had only mucous membrane covering it, and it had evidently started in the muscular walls.

61. **Perineal Prostatomy for Gonorrheal Abscess Cures the Gonorrhea.**—Cealic and Strominger report twenty-two case histories, all showing that perineal evacuation of a gonorrheal abscess in the prostate is a simple and excellent measure, as it not only cures the local lesion in the prostate but it facilitates the cure of the gonorrhea as a whole, even in cases in which it had long resisted the ordinary measures. They advise prostatomy without delay as soon as the diagnosis is made. In one case typical of many in their experience the abscess perforated into the rectum and the patient felt relieved and treatment was restricted to massage and lavage of the urethra. The prostate persisted large and tender and traces of the urethritis were evident for a year, when the prostate swelled again with perceptible fluctuation and fever. Prostatomy was done at once and the gonorrhea was eradicated.

64 Synthetic Purgatives. (Les purgatifs synthétiques.) A Martinet.
65 Specific Precipitin Reaction in Meningococcus Cerebrospinal Meningitis. Collignon and Pilod.

63. **Diagnosis of Duodenal Ulcer.**—Meunier has found it possible to diagnose a duodenal ulcer by rinsing out the stomach with a 1 per cent. solution of glacial acetic acid. Under the

influence of this acid fluid the pylorus shuts up and thus prevents the fluid from passing along into the duodenum. At the same time, if the ulceration is in the stomach, the acid solution dissolves the crystals of hematin found on the surface of a relatively recent raw surface. The positive reaction indicating the presence of blood in the rinsing fluid thus indicates ulceration in the stomach. The absence of traces of blood in the rinsing water, in connection with the symptoms suggesting duodenal ulcer, such as paroxysmal tardy pain in the stomach region—all this points to a duodenal ulcer. In every case in his experience in which the acetic acid reaction in the stomach rinsing water was positive, the following operation confirmed the presence of an ulcer in the body of the stomach. In two patients the reaction was negative. One was operated on by Moynihan at Leeds and the other by Pauchet at Amiens, and in each case the diagnosis of an exclusively duodenal ulcer was confirmed. The acetic acid test of the rinsing water of the stomach should be supplemented by examination of the stools for traces of blood. If blood is found in the stools and none in the rinsing water of the stomach, this locates the lesion below the stomach and it is almost invariably to be found just below the pylorus.

Semaine Médicale, Paris

September 13, XXXI, No. 37, pp. 433-444

66 *Dangers of Alkaline Intravenous Injections; Toxic Effects of Sodium. (Les dangers des injections intraveineuses alcalines; effets toxiques du sodium.) L. Blum.

66. **Dangers of Intravenous Alkaline Injections.**—Blum is convinced that many symptoms and disturbances observed after injection even of saline solution are due to the sodium chlorid in itself, recent research on "salt fever" in infants having revealed unsuspected pathogenic properties in it. It is certainly safer to use a physiologically balanced solution, adding a little alkali to the salt solution, as the physiologists have long been doing in their research. With alkaline solutions the problem is even more difficult, Blum's clinical experience with them having demonstrated the possible mishaps liable from their use. In two patients drifting into diabetic coma, the injection of a 2.5 or 5 per cent. solution of sodium carbonate was followed in about four hours by convulsions and death. The injection was difficult on account of spasmodic contraction of the vessels preventing the infusion. When it finally succeeded, the walls of the vessels were evidently injured by the alkaline solution as the blood infiltrated into the surrounding tissues the entire length of the vein. The symptoms of intoxication in both these cases, as also in two other patients who had been given a preceding injection of sodium glutarate, testified to the toxic action of the sodium. Many clinicians, including Frerichs and Naunyn, have never witnessed convulsions in the course of diabetic coma, and Blum has been able to find records of only six cases of the kind in the literature. His experience with only these four cases, in his twenty-five of diabetic coma, in which fatal convulsions developed after the alkaline injection, when he never witnessed anything of the kind before and none since he has abandoned the use of these alkaline solutions, points to the injections as the causal factor. Two of the patients thus succumbing were girls of 15 and 16, the others women of 23 and 71, all with diabetic somnolency but not amounting to coma in every case. Blum refers parenthetically to Labbé's recent report of an old diabetic, a woman of 65, of a diabetic family, who seemed to be lapsing into diabetic coma. He made an intravenous injection of 500 gm. of a 3 per cent. solution of sodium bicarbonate daily for five days, while the patient took about 70 gm. of sodium bicarbonate by the mouth: she gradually recovered and is now in good condition. Labbé added that he knows of only seven other cases on record in which diabetic coma failed to terminate fatally. He has also reported equally favorable results in a second, less severe case, after two intravenous injections of 15 gm. of sodium bicarbonate in a 3 per cent. solution, the patient a woman of 52, diabetic for twelve years. Blum further refers to the fact that Stadelmann has emphasized the importance of using the sesquicarbonate of sodium instead of the carbonate or bicarbonate as better tolerated than the carbonate while containing more sodium than the bicarbonate. It is produced merely by heating the solution of sodium bicarbonate, thus permitting some of the carbonic acid to escape.

70 *Action of Dissolved Tubercle B immunisatorische Verhalten d nebst Tuberkulinstudien und T H. Much and E. Leschke.

67 to 70. **Importance of Various Elements of Tubercle Bacilli for the Clinical Reaction.**—Much and Leschke believe that they have established that the fat, the albumin and the aromatic substance in the tubercle bacilli each play a part in the reaction to tuberculin, and that it is possible to isolate these various elements and induce a reaction to each separately. Each of these elements is able to induce a hypersusceptibility and induce the production of antibodies for each of these elements separately. The reaction in different persons thus may be of an entirely different nature, either an albumin-antialbumin reaction, a fat-antifat reaction or a toxin-antitoxin reaction, or all of these reactions may occur at once. By the complement-binding tests it may be possible to determine which of the above antibodies is lacking in the individual case, and by vaccinating with the antigen in question induce durable immunity or a complete cure. The organic acids seem to be most effectual in separating the tubercle bacilli into these elements, which is a different matter, they explain, from simple dissolving of the bacilli. They prefer for it the term *Aufschliessung*, which means an unlocking, and state that this conception of partial antibody production and partial antigens opens a new horizon for vaccine therapy with partial antigens.

81* Operative Treatment of Metastatic Carcinoma of the Spine. (Chirurgische Eingriffe bei metastatischen Karzinom der Wirbelsäule.) A. Tietze.

76. **Fractures and Roentoscopy.**—Plagemann tabulates the details of 3,664 fractures treated at the Rostock surgical clinic, 1891-1910, and compares the ultimate outcome with the roentographic findings in a large number. He remarks in conclusion that the Roentgen rays have simplified the diagnosis of fractures and have been of great aid as a guide to treatment, but still they are of little use and even misleading with certain fractures, such as fracture of the base of the brain. In a number of other fractures, also, the injury of neighboring organs has more to do with the ultimate outcome than the fracture of the bone itself. The chief advantage of the Roentgen rays is that they permit constant oversight of the objective condition later.

81. **Operative Treatment of Metastatic Cancer of the Spine.**—Although a radical cure is not possible, yet immense relief can be obtained by a palliative operation in these cases, and Tietze has applied it in five of his six cases of the kind. The patients were women from 32 to 54 years old and the primary cancer had been in the breast which had been amputated from a few months to three years before. The findings are illustrated in the operative cases. The benefit from the operation was great at first but did not last longer than a few weeks, except in one case. This patient was delivered from her agonizing pains and lived for more than a year in a satisfactory condition, dying then of pneumonia. In considering a palliative operation of the kind, the comparative malignancy of the primary cancer is an important factor to be borne in mind in estimating the possible benefit from the operation.

82. **Resection of Liver for Cancer.**—Klose reports what he thinks is the first successful resection of the entire left lobe of the liver for cancer. His patient was a man of 45. He died a few days afterward from fulminating endocarditis affecting a heart already in chronic fatty degeneration. Necropsy showed that the operation on the liver had been a complete success and that there was no trace of metastasis. The first symptoms of the cancer had been noticed six months before in the form of occasional stomach cramps and oppression, but no vomiting or jaundice. The stomach region began to protrude after four or five months, the man lost 42 pounds in weight. He was a manufacturer, well nourished, and the solid tumor palpated in the epigastrium could be pushed about within a range of 15 cm.; it was apparently independent of the stomach.

88. **Operative Neurology.**—Auerbach reviews the history, achievements and outlook for operative treatment of exophthalmic goiter, hysteria, epilepsy and brain, spinal cord and peripheral nerve affections. Rehn, in whose honor the bulky volume is issued, was the first in Germany to attempt operative treatment in exophthalmic goiter. The experiences to date indicate that the slightest tendency to myxedema formally contra-indicates an operation on the thyroid, and myodegeneration of the heart is also a dangerous element, although a complete cure or great improvement has been realized by some surgeons even in these very severe cases. Auerbach has himself had an experience of this kind. If the patients are wage-earners, he advises not delaying more than two or three months for a trial of vigorous internal measures before applying operative treatment, but, when possible, he prefers a six-months' course of medical treatment before resorting to strumectomy. He protests against the general hospital for such patients on account of the inevitable nervous shocks encountered there: such patients do better under oversight in the home or, better still, in convalescent homes, which are the crying need of the modern hospital system, especially for care of the severer nervous affections.

92. **The Blood Count for Diagnosis and Prognosis in Surgery.** Lampé has been applying F. E. Sondern's method for the differential leukocyte count and has become convinced of its value for both diagnosis and prognosis. The twenty cases he reports confirm Sondern's statements in every particular, with one possible but not certain exception. He also reports experimental research which gave still further confirmation of Sondern's views and of the value of his "resistance curve." "It permits," Lampé says, "an amazing insight into what is going on in the organism, reflecting as in a mirror the fight the body is putting up against the invading infection. Every repulse and every victory can be overlooked, and in the puzzling cases the method is of extreme importance; of course, it is not needed in the cases in which conditions are plain before the eyes without this aid."

86. **Extradural Spinal Cord Tumors.**—Siegel recently operated in two cases of this kind with complete success, although the tumor was secondary to cancer elsewhere, which has already proved fatal in one case, about a year after the operation. The patient was a man of 30 and the tumor removed was of the adenomacarcinoma type. The other patient was a woman of 33 with a small goiter for the last six years which had never caused any disturbances. The tumor removed from the spinal cord proved to be a metastasis of the struma. Siegel reviews the cases on record of metastasis from an apparently benign struma. The metastasis was generally in a bone and nothing malignant could be found in the thyroid after death in the cases in which necropsy was possible, except in Huguenin's case; in the others the findings were merely those of a colloidal goiter or normal thyroid. Riedel has had a case in which a metastasis of this kind recurred in the jaw ten years after removal of the first metastasic tumor, and yet the thyroid has been apparently normal all the time.

98. **Experiences with Tumors in the Large Intestine.**—Schmidt concludes from his sixty-three operative cases that resection and suture at one sitting give the best end-results, especially or care of the severer nervous affections.

108. **Movable Cecum.**—Klose reviews the history of operative treatment of conditions resulting from sagging of any portion of the gastro-intestinal canal, and discusses the subject from the standpoint of embryology, anatomy, physiology and symptomatology, especially the clinical picture of movable cecum. He states that 134 patients in this latter category have been given operative treatment at Rehn's clinic, including twelve children, and 75 per cent. were under 25 years old. In 70 per cent. the trouble was evidently of congenital origin. The main symptom was intermittent afebrile or subfebrile colic pains, like neuralgia, generally localized in the right side. There was also a localized elastic resistance in the ileocecal region, an air-cushion sensation on palpation, with ileocecal gurgling or splashing, increased peristalsis during the attacks, constipation followed with diarrhea, admixture of blood and mucus with the stools and carbohydrate fermentation. Klose remarks that the question of "pseudo-appendicitis" and "intestinal hysteria" needs to be studied anew by the internists as this assumption of a movable cecum has knocked out most of the foundation for them. Roentoscopy showing retarded peristalsis in the cecum shadow is typical for the movable cecum. Patients with this anomaly are liable to wander from one doctor to another, finding no relief, their disturbances being unjustly classed as neurasthenic, while operative fixation of the movable bowel clears up the diagnosis and generally cures the patient at one stroke. He gives the details of a few typical or unusual cases and of cases showing how the anomaly spreads to involve other parts of the bowel the longer it is left untreated. He concludes with an illustrated description of the preferred operative technic; the curving incision is unusually long and the cecum is sutured throughout its entire length to fasten it in place, taking up in the suture only the serosa of the bowel and fastening the bowel as far back as possible. When the ptosis is universal, he prefers a long incision in the median line, curving around the umbilicus; in one case illustrated the sagging large intestine, spleen and liver all required fixation.

109. **Posttraumatic Cancer.**—Löwenstein published last year a compilation of 271 cases of cancer developing apparently in connection with a trauma and adds nine more cases to the list here. This research indicates that we must now reckon with the effects of a single trauma as liable to induce the production of cancer just as certainly as we accept chronic irritation as a factor. He discusses the connection between the accident and the cancer from the standpoint of industrial insurance, and states further that his experience with disinfectants in treatment of inoperable cancer and in prophylaxis after operations—especially with large doses of quinin, santonin and thymol, given by the mouth or injected into the muscles or parenchyma or directly into the tumor—all the phenomena and results obtained have converted him to the view that a parasitic origin of cancer is not so impossible or improbable after all.

116. **Diagnosis of Arteriosclerosis of the Legs.**—The importance of detecting and locating arteriosclerotic changes in the vessels of the legs in diagnosing intermittent claudication and similar affections is emphasized by Rosenbusch. He applies the Strauss turgosphygmograph at different points along the leg. This records the volume of the pulse-wave and thus shows at a glance the vessels or the segments of the vessels which are functioning defectively. It is able to reveal findings in this line at points inaccessible to palpation, and at all points is far more reliable than the latter, pointing out the portions of the vessel which can be relied on to do normal work.

118. **The Meiostagmin Reaction in Cancer.**—Leidi reports positive findings with the Ascoli technic in 80 per cent. of twenty cancer patients tested and in less than 8 per cent. of twenty-four patients with other diseases.

126. **Pleura and Lung Surgery.**—Martens reports a number of successful operations on the lungs or pleura such as were undreamed of before the introduction of the differential pressure procedures. Among them is a case of chondrosarcoma successfully removed from the anterior chest wall and pleura close under the clavicle. The defect left after excision of the focus was closed with a large flap drawn around from the axilla and mamma, with which the lung was directly covered after the lung had been sutured to the edge of the defect all around. In another case he yielded to the appeal of a patient and removed a recurrence of a mammary cancer in the chest wall after the breast had been removed for recurrence of a primary tumor in the mamma, the tumor alone having been merely excised six months before. As a rule he refrains from such operations for recurring cancer in the chest and in this case the patient succumbed not long after to recurrence elsewhere. But the operation proved comparatively simple and easy, a large portion of the sternum and of three ribs being cut out with shears, leaving the lungs, pericardium and pleura exposed. He sutured the lung to the edges of the defect and twisted the remaining mamma around to close it. Healing was complete so that the patient was dismissed in twelve

days. In another case he resected part of two ribs to locate a bronchiectatic cavity in the lungs. When found he did not attempt to evacuate it, but sutured the pleura again and then evacuated the cavity by puncture with the actual cautery. He had a similar success in another case in which he opened into the cavity with the actual cautery, finding it at a depth of 5 cm. from the surface and 13 cm. in extent. He discusses the various technics for differential pressure, his work having been done mostly with the Brat-Schmieden positive pressure mask method.

128. **Old Congenital Dislocation of the Hip.**—Patschke reports the successful correction of congenital dislocation of both hip joints in a woman of 26. He scooped out a new cavity for the head but broke off the head in fitting it into the new cavity. The neck stump answered every purpose, however, and the functional use of the limb was restored. A similar operation was then done on the other hip joint six months after the first and without a fracture this time, so the patient was restored to practically normal gait and endurance. Her deformity had not caused her much disturbance till her eighteenth year, so she had never consulted a physician on account of it, but after that year she became unable to walk and no benefit was derived from long systematic courses of medical and orthopedic measures.

135. **Modifications of the Reflexes and the "Calf Reflex."**—Trömner has been examining the reflexes in twenty cases of recent nervous disease and in forty cases of long standing, and tabulates the compared findings. He remarks that it is generally possible to elicit the Babinski sign by the usual technic, but in dubious cases he applies a stronger method, pressing with a rapid hard pressure in the middle of the arch of the foot, below the ball of the great toe. This not only entails extension of the great toe but possibly also flexion of the foot, knee or thigh, or all together, in the pathologic cases. Sometimes the reflex followed when the foot was thus grasped firmly; in others it occurred only when the pressure was abruptly released. This Babinski-pressure phenomenon is more constant and more sensitive than the ordinary Babinski or Oppenheim signs and it is pathognomonic, he asserts, for foci above the lumbar region and it is less liable to be misinterpreted while it needs no instrument except a firm hand grasp. He has also found that the easiest way to induce the Oppenheim phenomenon is by applying strong brief pressure to the inner margin of the tibia, at a point between the middle and lower thirds. He presses forcibly with his thumb, the other fingers grasping the outer edge of the tibia, and the great toe is extended while the knee and hip joints flex—thus the same reaction as with the Babinski-pressure sign. The pressure must be made strong enough to hurt a little in the dubious cases. He also calls attention to what he entitles the "calf reflex," *Wadenphänomen.* It is a dorsal flexion of the foot when the hollow of the half-flexed knee is grasped from the inside and strong rapid pressure applied stroking downward as if to massage centrifugally the gastrocnemius muscle. The leg is held half bent and rotated outward, supported by the other hand. Dorsal flexion of the foot is the pathognomonic reflex; sometimes it may include flexion of the knee and hip-joints. In his study of the various reflex phenomena in forty cases of organic nervous affections of long standing and in twenty recent cases the calf sign was found in seventeen of the recent and in thirty-eight of the old cases, and the modified other phenomena in nearly as many, while with the usual technics the Babinski was elicited only in fifteen of the recent and only in thirty-three of the old cases and the Oppenheim only in twelve and eighteen, respectively. He was careful to make the tests allowing ample pauses between to exclude the influence of fatigue. The Bechterew-Mendel phenomenon can be elicited by merely tapping on the ball of the great toe or sole of the foot. This reflex occurred in five of the recent cases and in twenty-nine of the old, and the Rossolino reflex in the same number, coincident in all but one case. Trömner does not claim that the modifications he describes are new, but only emphasizes that the technic is simpler and more sensitive than those hitherto in vogue.

136. **Toxic Symptoms After Intravenous Injection of Salvarsan.**—The dose injected had been only 0.28 gm. but the signs of intoxication were extremely severe, including total anuria for over twenty-four hours. Study of them has, however, convinced Marschalko that the drug itself is not responsible for them but rather the vehicle in which it is administered as he explains in detail. He ascribes the disturbances to the germ content of the salt solution or distilled water. During the hot weather especially, a prolific microbian vegetation flourished in the water, and although it was killed by boiling the water, yet the germs persisted as albumin-containing bodies which are liable to induce serious intoxication if introduced directly into the circulation. The only means to avoid this is to redistil afresh the water to be used for intravenous injections, and then boil it for half an hour before adding the salt solution or drug. In his case the patient had chills, vertigo and high fever, vomiting and diarrhea, with great depression. The symptoms gradually subsided so that by the fourth day he felt entirely well. In all his other 400 patients there was no reaction or it was moderate, passing over before nightfall.

148. **Leukocytosis with Perforated Gastric Ulcer.**—Mannheimer's experience with twelve cases, which he reports in detail, confirms the advantages of watching the curve of the neutrophil leukocytes as an index of the virulence of the inflammation and of the resisting powers of the organism after perforation of a gastric ulcer. The curve is not so regular as with appendicitis, as the hyperleukocytosis does not develop until the peritoneum begins to be inflamed. But this very fact, with others, makes the differential blood-count exceptionally instructive.

149. **Mechanical Predisposition of Lung Apex to Disease.**—Baemeister reports the details of experimental research in which he succeeded in inducing an isolated tuberculous process in the apices in animals. Injection of cinnabar into the circulating blood and inhalation of soot both confirmed the fact of the impeded circulation and respiration in the apex, hampered by certain artificially induced mechanical conditions. He never succeeded in infecting the apex in animals by having them inhale infectious material, but by injecting the material into the blood he regularly and constantly induced a focus in the apex when the mechanical conditions had prepared a predisposition. The research reported confirms the etiologic assumption of the injurious influence of a rigid and confined upper part of the chest, and justifies chondrotomy or any other means aiming to restore normal mechanical conditions and put an end to the stenosis of the upper aperture.

150. **Disturbances in Taste with Brain Tumors.**—Scholz urges closer study of this subject, citing Funkenstein's case in which the combination of paralysis of the nerve of taste with paralysis of the auditory nerve, while the facial, fifth and glossopharyngeal nerves were intact, led unerringly to discovery of a tumor in the posterior cranial fossa. He reports a case from his own experience in which a neurofibroma in the cerebellopontine angle had induced, besides the usual symptoms, paralysis of the taste in the regions innervated by the intermedius. He discusses the anatomy of the nerves involved, with a diagram.

157 Malignant Melanoma of the Vulva. N. Markus.

152. **Inherited Syphilis.**—Baisch urges that the puerperium is an excellent time for commencing treatment of syphilis and that apparently healthy women bearing syphilitic children will consent to treatment then who heedlessly disregard the necessity for it a few weeks later as they feel well. He has had a case of rupture of the uterus from syphilitic changes, which were also responsible in another case for premature separation of the placenta. He advocates salvarsan treatment of all syphilitic pregnant women and parturients, and reports thirty cases in which this was done during the puerperium. In three cases salvarsan treatment during the pregnancy was well borne and seemed to have a favorable influence on the offspring, all three being apparently free from syphilis, but the blood from the umbilical cord in one gave a weak Wassermann reaction. These three women had aborted at each preceding pregnancy.

156. **Operative Treatment of Chronic Inflammation in Ovaries or Tubes.**—Operative treatment was applied in only ninety-three of the 2,633 cases in this category at Wieden, 1902 to 1910. Three-fourths of these patients have been reexamined recently, after at least a year since the operation. The findings on reexamination teach that conservative treatment should be perseveringly applied but that if operative measures become necessary, the operation should be radical; conservative, half-way surgical measures cannot be relied on for a permanent cure.

169 Vasoconstricting Substances in Serum in Rachitis, Tetany and the Exudative Diathesis. H. and L. Hirschfeld.

160. **Diagnostic Importance of Emotional Fluctuations in the Pulse.**—Schrumpf and Zabel report experiences which show that the rigid vessels in arteriosclerosis are unable to compensate the emotional changes in the heart-rate, and consequently the radial pulse reflects them. Any fluctuations in the diastolic blood-pressure of psychic origin, which amount to more than 15 per cent. of the systolic fluctuations, testify to the presence of arteriosclerosis.

162. **Premature Sensation of Having Eaten Enough.**—Neisser and Bräuning have had some patients who grew thin because their appetite was appeased with a few mouthfuls of food and they did not care to eat more and consequently were starving although their appetites were good. Experimental and clinical research was undertaken to determine the mechanism of the feeling of satiety, and they found that it depended on the pressure within the stomach. This pressure may be from the food itself or from the peristaltic contraction of the stomach or from pressure from without as from a tight corset. The peristaltic contractions of the stomach are started by the act of swallowing; they found that by pouring the food into the stomach through a tube, thus avoiding swallowing there was no sensation of satiation until much later than when a much smaller amount of fluid had been swallowed naturally. The research reported indicates that there is the same delicate and constant connection between the motor functioning of the mouth and of the stomach as between the secretory functioning of mouth and stomach to which Pawlow called attention. Besides laying aside the corset, some suggestion was needed to train the young girls to eat normally and enjoy the entire meal with appetite instead of being satisfied with a few mouthfuls, but this once accomplished they rapidly took on weight. None of his girl patients was unduly nervous or hysteric. In another group of patients the early satiation was traced to excessive tonicity of the stomach walls and hasty eating. When they were trained to eat more hygienically they soon became normal eaters. He found it a help in treating these patients and others with various stomach troubles, to have them recline while taking their meals. This seemed to alter the pressure within the stomach in some beneficial way.

163. **Specific Cancer Reactions.**—Stammler has been testing the various ferment reactions that have been proposed as an aid to the diagnosis of cancer, and has found that the meiostagmin reaction is frequently a most valuable aid for differentiation of dubious conditions. He examined the serum of 340 patients with various affections, including 120 with certain cancer, and obtained a positive reaction in 73 per cent. of the cancer cases. At the same time he warns that a positive reaction was obtained also in 20 per cent. of the patients with other affections, mostly diphtheria and scarlet fever, diabetic gangrene and enlargement of the prostate. The reaction, however, was never positive in cachexia of noncancerous origin. [The technic for the meiostagmin reaction was described editorially in The Journal, May 28, 1910, page 1780.] Stammler in studying these various reactions happened on another which he thinks may prove of value. It proved positive in 82 per cent. of the 100 tumor patients and only in fourteen of the 130 patients with other affections examined. The technic is the same as for the meiostagmin reaction, only both serum and antigen are used less diluted. The mixed fluids are set in the autoclave for six hours and then set aside to cool gradually. With the cancerous serum precipitation soon occurs, leaving the supernatant fluid clear, while the precipitation with non-cancerous serum is very slight and the fluid persists turbid. He used an extract of a recently excised liver carcinoma, adding to 2 c.c. of the extract dilution 0.1 or 0.5 c.c. of undiluted serum. The findings were identical with this and the meiostagmin test. All the various reactions that he reviews are traceable to the presence of a special ferment in malignant growths.

164. **The Families of Paralytics.**—Plaut and Göring were amazed to find that the families of fifty-four persons known to have general progressive paralysis had so seldom been suspected of syphilis, and yet many of the consorts and children gave a positive Wassermann reaction and some of them presented unmistakable evidences of syphilis. They urge the necessity for investigation of conditions in the families of persons known to have syphilis, as an important task which physicians should not shirk.

165. **Modified Technic for Rhizotomy.**—Wilms and Kolb severed the sensory nerve fibers in the conoid distal end of the spinal cord, instead of the typical Dana or Förster operation, in three cases and commend this technic as liable to prove equally effectual, while it is a much less serious operation than the original technic. They describe their cases and analyze the anatomic conditions in the conus medullaris. The first patient had Little's disease and slight but decided benefit was apparent even from the timid tentative operation. The second patient was a man of 30 with spastic paralysis of both legs and great benefit was derived although a tendency to ataxia had to be overcome. This patient had bladder disturbances with retention of urine, and these were not modified by the operation. In the third case the contractures were due to athetotic spasm and the functional result was less good. The operation is so simple that scarcely ten minutes were required for it after the dura had been opened.

171. **Differences in the Radial Pulse Right and Left.**—Könnecke examined 500 persons, sick and well, and found the radial pulse alike on both sides in only 56 per cent.; in 2.5 per cent. there was marked difference. These differences in the pulse were traceable in some cases to purely local or slight central causes with otherwise intact vascular system. His practical conclusion is that the radial pulse on both sides should be tested and not one alone. The left pulse was the stronger in 14 per cent. of 455 right-handed individuals and in 43 per cent. of 21 ambidextrous. With persons over 45 the difference in the pulse is generally due to arteriosclerosis of the orifices of the arteries, if no peripheral changes in the artery wall can be detected.

172. **Digitalis in Treatment of Hemorrhage from the Lungs.**—Focke analyzes forty cases from his own experience and a number on record, his conclusions being that hemorrhage from the lungs is by no means due to tuberculosis in as large a proportion of cases as is generally assumed. Tuberculosis could be incriminated in only seven, that is, in a small per cent. of his cases. In three other cases there was pronounced anemia, in another furunculosis, in another nephritis. In twelve others there was a severe cough, from acute catarrh in five, with congestion in the head in one. In seven other cases there was chronic irritation of the air passages in elderly persons with asthma, bronchial ectasia or arteriosclerosis. The hemorrhage occurs almost invariably from local congestion, inducing diapedesis; rupture of a vessel is very rare. As the diapedesis occurs only from local stasis, treatment should aim to regulate the circulation in the region and for this nothing is so effectual as digitalis. The hemoptysis may not be threatening but it always frightens the patient and his family and it may run into something threatening, so that treatment should be instituted at once. The proper measures are those that put an end to the causal local disturbance in the circulation and prevent its recurrence, namely, by dietetic and medicinal measures, keeping the bowels open and regulating the circulation with digitalis. He generally orders for adults an infusion of the leaves.

191 *Simplified Sphygmomanometer. (Das neue Modell meines Blutdruckmessers.) M. Herz.

191. **Simplified Sphygomanometer.**—Herz has modified his blood-pressure indicator so that the pressure is regulated practically automatically while the entire attention of the operator can be concentrated on his palpation of the pulse. Even with this change in his original hemodynamometer, it is still, he asserts, the smallest and simplest of all apparatus of the kind in practical use. Fig. 1 shows at *a* the rubber armlet and leather strap, *h*; *b*, the manometer tube, is held horizontally in the patient's fingers, and *d* and *c* are the two clamps to control the supply of air from the bulb. The armlet is applied and strapped tight, the manometer tube held as in the illustration, the mercury at zero. Then with the clamp *d* closed, the ball *f* is pumped as full of air as possible, until its net is stretched to the utmost. Then the operator feels for the radial pulse with his left hand and with his right opens clamp *d*. The air penetrates very slowly into the cuff and the mercury slowly moves toward the farther end of the tube. The moment that the pulse disappears, the clamp *d* is closed again, so that the communication between the bulb and the cuff is again interrupted. Opening then the clamp *c* permits the escape of the air in the cuff and manometer, and the measurement can then be taken again. The

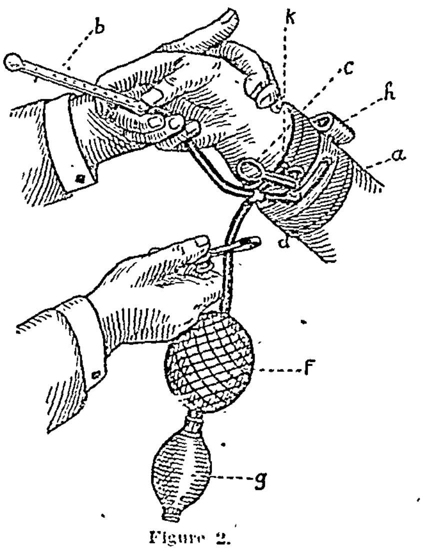

Figure 2.

special feature of the apparatus is that the stout-walled ball *f* serves as a reservoir for the compressed air. It holds enough air for the measurement to be taken over again three or four times. The apparatus further permits recognition of the diastolic pressure by the lessening of the radial pulse. The apparatus is completely emptied by opening both clamps at once.

198 *Importance of Albuminuria in Pregnancy and Puerperium. (Klinische Bedeutung der Albuminurie in der Schwangerschaft, bei der Geburt und im Wochenbett.) O. Jaeger.

192. **Treatment of Asphyxia of the New-Born.**—Schultze replies to Ahlfeld's recent statement that the swinging method is too dangerous, and recapitulates the directions for this technic. He remarks that one of the principal blunders that beginners may make with this method is to swing the child so slowly that it bends over backward. This is best prevented by letting the last three fingers of both hands lie along the back, thus supporting the child in the upward swing. The swinging may be done so vigorously that the pelvic end goes too far and the spine is flexed in the chest region. This exposes the intestine to danger of being crushed, while it permits no or only imperfect expiration. Or the swinging may be so gentle that the pelvis sinks sideways. To avoid this, as soon as it is seen that the swinging was too gentle, the child should be dropped into the inspiration position or, if one is lively enough, take half a step forward; the resulting compensation in the shoulder and elbow region will catch the child still in the expiration position. Practice will teach the proper medium between too vigorous and too feeble swinging, so that the pelvic end of the child will sink gradually on its thorax. But this practice must not be done *on the asphyxiated new-born child; that is too precious material for such* exercises. They should be done on infant cadavers.. He lays most stress on the supply of oxygen to the medulla oblongata which is attained by the swinging. At each swing about 20 c.c. of atmospheric air flows in and out of the lung, while the circulation of the blood is mechanically started at the same time. Without a supply of oxygen from without, as long as the circulation keeps up, the blood grows poorer and poorer in oxygen as it keeps yielding it up to the tissues. Nothing but a supply of oxygen to the medulla can revive its deeply depressed excitability. Although a hot bath may promote the circulation under other conditions, in the asphyxiated new-born child it can only aggravate the condition of the blood, augmenting its venous character. He regards the chilling of the skin as the best stimulus for the respiration when the child is only slightly asphyxiated. Only when the child does not breathe and cry after a few minutes of mild stimulation of the skin does he cut the cord, with as little loss of blood as possible, and then apply more vigorous measures.

Olhausen speaks a word in favor of blowing air into the lungs and also of letting a little blood escape from the umbilical cord in blue asphyxia when the symptoms seem to indicate that there is undue congestion in the inferior vena cava and right heart; the latter is not able to master its contents. He warns against too hasty and vigorous measures; the tender new-born must be treated differently from an older person or injury may result.

Nacke remarks that the Schultze swinging is probably done far too often and too much, but still the proper technic is rarely used. He wraps the child in a warm cloth, holding it across the back with the forefingers in the axillæ. He first dips the child in a hot bath, then in a cold, then rubs and if the heart is not working, massages the heart, and only when these fail does he swing it. He has found massage of the heart very useful, and thinks that the benefit from the swinging is due more to stimulation of the contractions of the heart than to stimulation of the respiration center. He percusses *the heart region with four fingers of his right hand*, thus tapping it elastically about three hundred times in a minute. The heart frequently revives after this even when no sounds had been perceptible from it with the stethoscope before.

196. **Relations Between Difficult Delivery and Nervous and Mental Trouble Later.**—Hannes has been investigating the present condition of 150 children born severely asphyxiated at the maternity at Breslau between 1893 and 1904. Also of a second series of 150 children delivered with forceps during the same period, and of a third series of 150 delivered spontaneously and normally. He sent a question-blank containing forty queries to the various families or filled it out himself from his knowledge of the children. The final conclusions from comparison of these groups are that difficult delivery has absolutely no influence on the nervous and mental condition of the child in later years unless there has been some direct injury of an organ, which is most exceptional. When the asphyxiated or forceps child survived the first week or so it developed thereafter the same as the normally born children, the proportion of cases of nervous or mental impairment being practically the same in each of the three groups, and the mortality in the first ten weeks being approximately the same. The data show further that the first-born children survive in much larger numbers than the children born to already large families.

198. **Albuminuria During Pregnancy and the Puerperium.**—Jaeger examined systematically the urine of 100 women during the last months of pregnancy and of 120 immediately after delivery. He found albuminuria in 70 per cent. of the pregnant women, and in 25 per cent. the albuminuria was of the orthostatic or lordosis type. Some latent bacterial influence is often responsible for the albuminuria and this influence may increase to actual direct injury of the kidneys during a later pregnancy or after delivery. He found tubecasts showing already pronounced injury of the kidneys in 11 per cent. With the lordosis type there were no tubecasts until after delivery. Albumin was almost invariably present in the urine during delivery and in larger amounts in primiparæ. Mechanical, toxic and infectious factors evidently are all involved in the albuminuria during pregnancy and childbirth, and also a constitutional predisposition on the *part of the kidneys in the lordosis type.*

199. **Diagnosis and Treatment of Horseshoe Kidney.**—Rovsing has encountered four cases of horseshoe kidney in the last seven years and states that this deformity should be suspected whenever a patient complains of oppressive pain across the abdomen from one kidney region to the other, which subsides entirely when the patient reclines on his back; especially when the pain is brought on by physical exertion and becomes intensely exaggerated when the spine is bent over backward, and a tumor can be palpated from the right or left side in front back to the spine. In two other cases this syndrome was manifest except that the pain was not essentially augmented when the spine was bent over backward and the pain did not subside as the patient lay down on his back. In these cases an operation revealed that the trouble was merely a tuberculous affection of some mesenteric lymph-nodes. The pain from horseshoe kidney can be relieved only by repose and avoidance of all physical exertion. Where this is impracticable, operative measures are indicated, and in his third case Rovsing restored approximately normal conditions by cutting the kidney through the center, thus dividing it into two parts, each of which slid into its normal place and the patient thus has now two approximately normal kidneys. His attempt to do this through the ordinary slanting lumbar incision proved impracticable in his first two cases; in the third case he reached the kidney by the transperitoneal route, outside of the colon and duodenum, thus reaching the center of the single kidney by a rather roundabout road, separating and lifting the peritoneum, leaving intact the mesentery over the isthmus part of the kidney, as the mesentery at this point had evidently suffered from chronic pressure from the kidney. The isthmus in this case was a mass of true kidney tissue, and he avoided the otherwise inevitable copious hemorrhage by applying the liver resection technic, slowly squeezing the tissues in the grip of an angiotribe until the isthmus was reduced to a ribbon, and suturing on each side after this ribbon was cut. The results have been so excellent that he intends to propose this operation to the two other patients.

205. **Operative Influencing of Kidney Secretion.**—Heresco operated in 1903 in a severe case of diabetes insipidus in a youth of 15. He exposed the left kidney, which was loose and displaced, and massaged the renal plexus with kneading movements and then restored the kidney to place with the Guyon technic. His aim was to influence the functioning of the kidney as sympathectomy influences the tachycardia in exophthalmic goiter. The results surpassed all anticipations, the polyuria and polydipsia subsiding at once, and permanently over eight years to date. The skin and muscles bled profusely as they were incised, but as soon as the stem of the kidney was kneaded between the fingers all hemorrhage ceased. In 1909 a similar operation was done on another patient, a young man with diabetes insipidus and both kidneys displaced, but the results were not so striking as in the first case although the patient was much improved by the nephropexy on both sides and kneading of the renal plexus. Heresco has been studying on animals the influencing of renal secretion by manipulating the renal plexus, and emphasizes the necessity for abstaining from the slightest contact with the renal plexus when operating in cases with a tendency to anuria as any manipulating of the kidney has an inhibiting influence on its secreting function.

216 *Staining of Living Tissues for Better Examination. (Ueber Färbung lebender Gewebe zu topographischen Zwecken.) Z. Slawinski.

215. **Arteriovenous Anastomosis for Angiosclerotic Gangrene.**—Wieting has performed this operation in five cases with excellent results, diverting the arterial blood into the venous system. These five were the only ones in his 150 gangrene cases in which the indications seemed to offer a prospect of success for this special technic, and the excellent outcome refutes, he declares, the theoretical objections that have been made against this operation.

216. **Staining a Fistula, Etc., to Aid in Diagnosing.**—Slawinski has found it of great assistance in excising a fistula passage to inject first a little saturated aqueous solution of methylene blue. The tissues take the stain and all the ramifications of the fistula are thrown into relief. The same technic is also useful at times to trace the course of normal passages. The stain is not washed away at once by the blood like bismuth paste.

221 Advantages of Local Application of Camphorated Glycerin in Gynecology. (Verwendung des Kampfers in der Gynäkologie.) R. F. v. Budberg.

217. **Serotherapy in Pregnancy Toxicoses.**—Mayer reports three additional cases with great benefit from three intravenous injections of 20 c.c. of serum from a normal pregnant woman. One patient was a young woman with severe eclampsia coming on during the sixth month of pregnancy. She was brought to the hospital in profound coma, no corneal reflex, pulse, 96 and tense; blood-pressure, 175; 7 per cent. albumin in the 80 c.c. of urine drawn from the bladder, but no distinct edema. The second injection was made after the twenty-first convulsion, the coma persisting unmodified except for transient rousing fifteen minutes after the first injection. In twenty minutes after the second there were signs of returning consciousness and after two hours another and the last convulsion followed, and improvement then rapidly progressed. A third injection was made at the seventh hour and spontaneous delivery followed in less than nine hours after the last convulsion. No other remedies were given. In another case the pregnancy intoxication manifested itself in numbness, itching or formication, all subsiding after an intravenous injection of 10 c.c. of serum from a normal pregnant woman. The third patient had severe and extensive herpes over the body which persisted for two months till delivery, and became much aggravated thereafter. An injection of 20 c.c. of normal pregnancy serum was then made, intramuscularly, as no site for an aseptic injection into a vein could be discovered. Improvement followed at once; two more injections were made before the whole body was freed from the herpes.

224 Immunizing Properties of Desiccated Tuberculous Sputum. (Proprieta immunizzanti dell'espettorato tubercolare disseccato al calore.) G. Romanelli.

222. **Syphilis of the Stomach.**—Mathieu gives a historical review of syphilitic lesions of the stomach from Andral's two cases in 1838 to date, citing in particular from Fournier's work on syphilis of the stomach in which he described two cases of "false cancer of the stomach;" a tentative course of mercurial treatment was almost casually instituted before the contemplated operation to remove the tumor palpated in the stomach, and in a few months all trace of the cancer had disappeared. In other cases the syphilitic lesions simulated cancerous stenosis at the pylorus or induced ulceration or changes in the shape of the stomach resulting in hour-glass stomach. In one of the cases cited the pylorus was resected before the syphilitic nature of the lesion was ascertained. In other cases the syphilitic stenosis at the pylorus continued to progress notwithstanding vigorous antisyphilitic measures. In another case an actress with a history of syphilis had apparently a hemorrhagic gastric ulcer, rebellious to ordinary measures but healing at once under potassium iodid. The patient had a recurrence a few years later while travel-

ing but no physician would heed her requests for antisyphilitic treatment for the hemorrhagic ulcer, and she used up nearly her last remnant of strength in traveling back to her old physician who again banished all symptoms by vigorous potassium iodid treatment. In another case a man was on the point of having an operation performed to relieve the disturbances from an hour-glass stomach, the change in shape having apparently come on gradually. A tentative course of antisyphilitic treatment induced striking improvement, and the stomach subsided more and more toward normal shape. There was evidently gummatous induration in the stomach wall shriveling and drawing it up at this point and thus separating it into two parts. In every case of severe stomach disturbances in a patient supected of syphilis, the possibility of a syphilitic origin should be borne in mind. The coincidence of tertiary syphilitic lesions elsewhere should suggest a tentative course of specific treatment.

228 *Quack Humbug. (Arkana og Kvaksalvere.) V. Lassen.

228. **Quack Humbug.**—Lassen tells of some of the most flagrant examples of quack practices in Denmark, especially the orthopedic appliances made by quacks and sold at high prices as a remedy for all kinds of diseases and deformities. He gives an illustration of one, for instance, a harness of leather and metal comprising a corset fitting from axillæ to thighs, broad bands strapped around the thighs, calves and ankles, the harness fitting over the shoulders and under each foot—this complicated and expensive contrivance was fitted to an adult man solely for the purpose of correcting a pes valgus. Lassen asserts that the medical profession ought to use its influence in particular to obtain legislation requiring that permission must be obtained from the authorities before electric belts and the like can be advertised or sold, and that physicians and quacks in other countries shall not be allowed to advertise in Denmark without special permit, and that no one shall be allowed to make or sell orthopedic appliances without special training and having passed an examination by a board comprising at least one physician and one skilled orthopedist, and that the appliances must be made only on a physician's prescription and only when the appliance-maker takes the measurements himself. Lassen did not ask the medical society before which he was speaking to vote on these suggestions but he did appeal to the society to call the attention of the public health authorities to the damage wrought by unscrupulous quacks with their ill-fitting, gangrene-inviting bandages and harnesses which they sell for osteomalacia and all kinds of affections, robbing the poor right and left. He knows of many a family where a cow was sold to buy the electric belt or harness. He adds that not a few unthinking persons will ascribe such efforts on the part of the profession to professional envy, but he says that the medical profession never competes with quacks in selling electric belts and the like, and that it certainly will be able to prove its disinterestedness in wishing to place the making of orthopedic appliances in the hands of those specially qualified for the work. Lassen mentions parenthetically a certain James Kidd who lives in America and advertises extensively in the Danish papers that he will cure all diseases gratis. Lassen has ascertained that Kidd sends the same advice to all who apply to him, regardless of the symptoms they describe, and, of course, he has to be reimbursed for the medicines he sends. A postman has told Lassen that over $100,000 is sent out to Kidd every year from Denmark.

PRIMARY CARCINOMA OF THE FALLOPIAN TUBE *

E. E. MONTGOMERY, M.D.
Professor of Gynecology, Jefferson Medical College
PHILADELPHIA

It is a well-known fact that no portion of the body is immune to the invasion of carcinoma. The more ready exposure of certain portions of the structure to traumatism renders its appearance in such tissues more probable. It is not surprising, then, that the cervix, exposed as it is to frequent injury in coitus and the course of pregnancy, should be the most frequently involved.

The many changes to which the active cellular structure of the ovary is subject render it particularly vulnerable to cancer, and authorities agree that probably 20 per cent. of ovarian tumors will prove malignant. Situated as the tube is, between two such vulnerable organs and in direct functional relations with them, it could scarcely be seen how extension from these structures to the tube could be avoided.

Notwithstanding the frequency of cancer in the ovary, the investigations of Orthmann would seem to show that carcinoma is rarely transmitted from it to the tube. It is true that 8 per cent. of all reported cases of tubal cancer are associated with tubo-ovarian cysts, but careful observation indicates that the disease was primary to the tube and had been projected into the ovarian portion.

In seeking a cause for such involvement it is found in the irritation cells which result from tubal inflammation. In all the cases, carefully observed, the malignant disease has been preceded by long-continued tubal inflammation. Inflammatory conditions of the tube are so frequent that abundant opportunity exists for development.

Primary carcinoma of the Fallopian tube is regarded as a rare affection, and it is rare, when compared with the frequency of carcinoma in the uterus. The investigations of Orthmann, Boxer and others, have demonstrated its occurrence more frequently than supposed. While sarcoma and chorio-epithelioma have been found, carcinoma is much more frequent.

Boxer, in his contributions to the knowledge of tubal carcinoma, has analyzed 100 cases.

In its early stages the disease presents no symptoms which are likely to awaken the fears of the physician. Indeed, the gravity of the condition may be overlooked when the patient is subjected to operative procedure, unless the specimens removed are as a routine procedure subjected to microscopic investigation.

The most frequent symptom is menorrhagia, and a watery discharge is not infrequent. Pain as a consequence is rare. It is true the patient may complain of an uncomfortable sensation in the affected side of the pelvis.

The symptoms enumerated are common to a number of conditions within the pelvis, and take place in women who have had prolonged or repeated inflammatory attacks. The appearance of such symptoms in women who have pelvic disorder, and especially a thin, watery discharge, should be an indication for early operative interference.

The neoplasm, even when exposed, does not always present an appearance which should warn the operator of its gravity. While the largest percentage of reported cases occur between the ages of 45 and 50, the proportion is not sufficiently great to be of any diagnostic importance. It has been found in women who had passed the sixtieth year, and as early as the twenty-seventh year.

The occurrence of menorrhagia and watery discharge in women who have been victims of pelvic inflammation, when found associated with enlargement of the tubal structure should be regarded as danger-signals of sufficient importance to demand investigation through an operative procedure.

Neoplastic rather than inflammatory involvement indicates radical removal. When both tubes and ovaries are involved in neoplastic change, or the tubes only, the operative procedure should include the removal of uterus and ovaries as well as the tubes.

The diagnosis of malignant neoplasm cannot be made from the macroscopic appearance only. No case should be accepted as malignant when such diagnosis is not confirmed by the microscopic findings.

A very interesting case illustrating the importance of the position I have just stated was sent by me to my private service at the Jefferson Hospital, Sept. 9, 1910.

History.—The patient was aged 34 years, married twice, but never pregnant. The only constitutional condition incident to the family was tuberculosis, although none of the immediate family had died of it. The patient's husband informed me that his wife's first husband had died of cancer. Puberty was established at the age of 14. Periods were regular, profuse, painless, and lasted four to five days. She had been treated for pulmonary tuberculosis during the last two years, but had apparently recovered. Five months before coming under my observation she began to experience pain in the pelvis for four or five days preceding menstruation. The menstrual periods occurred every three weeks, lasting three to four days, and were very profuse. She had also noticed during this time a whitish discharge.

Examination.—This disclosed a retroversion of the uterus, and behind it to the right was a mass the size of an English walnut, which was quite movable. Diagnosis was retroversion with endometritis and a prolapsed right ovary.

---

* Read in the Section on Obstetrics and Gynecology of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Operations.—The patient was subjected to operation on September 10. The uterus was dilated and curetted, and the abdomen opened by the Pfannenstiel incision. The mass on the rignt side was found to be a neoplasm of the end of the tube, which was not adherent but freely movable. It was removed. The left tube was adherent and considerably thickened in its central portion. I contented myself with separation of the adhesions, and proceeded to shorten the round ligaments by carrying a loop of each between the layers of the broad ligaments and through the aponeurosis. The appendix was removed, although it presented nothing of an inflammatory character. The neoplasm, when cut through, gave the appearance of a fibroid which was undergoing fatty change. Microscopic examination disclosed the growth to be cylinder-cell carcinoma.

This report reached me on September 23, and the following day I removed the uterus, the remaining tube, and both ovaries. I was impelled to do this by the fact that at the previous operation I had found the left tube considerably thickened in its central portion.

Postoperative History.—With the exception of a slight phlebitis of the left leg, which developed on the fifth day after the second operation, the convalescence was very satisfactory. The patient was discharged in good condition Oct. 22, 1910. A week later some induration occurred at the lower angle of the wound, and a small quantity of sero-purulent fluid was discharged. A sinus discharging very slightly persisted for some months before it finally healed. It was difficult to account for this, as no silk was employed, either as ligatures or buried sutures. At the end of eight months the patient had gained 50 pounds, and seemed in the best of health. The uterus removed, aside from a small interstitial fibroid, was in good condition. The left tube the pathologist reported to be a tuberculoma.

This patient, but 34 years of age, presented the anomalous condition of carcinoma in one tube, tuberculosis of the other, and a myoma in the uterus. Her future cannot but be interesting.

CONCLUSIONS

The study of the cases which have been reported by a number of observers would seem to justify the following conclusions:

1. Menorrhagia and watery discharge occurring in women giving a history of previous tubal inflammation should be regarded as danger-signals demanding careful investigation.
2. The association with such symptoms of tubal masses should be considered as requiring their removal, and where both tubes are involved the removal of the uterus through an abdominal incision.
3. All neoplastic masses of the tube should be subjected to microscopical investigation, for only thus can the diagnosis as to malignancy or non-malignancy be accurately determined.

1426 Spruce Street.

Scientific Investigation vs. Theorizing and Speculation.—The utter futility of the speculative method as a means of attaining effective knowledge is completely demonstrated by the stagnation and inefficiency of medicine under its influence for thousands of years. The only sure and effective way of gaining knowledge is the empirical method, by patient observation and investigation, the tardy adoption of which was the sole means by which internal medicine has been revolutionized and vivified. The keynote of the true method was struck by John Hunter in his advice to Jenner when the latter was beginning to ponder on the subject of vaccination, "Do not think, investigate." The whole history of medicine is an imposing demonstration of the futility of theorizing and the utility of scientific investigation.—Nichols in *Popular Science Monthly.*

A MILK-BORNE EPIDEMIC OF TYPHOID FEVER

AND THE DEMONSTRATED VALUE OF THE WIDAL REACTION IN DETECTING A TYPHOID CARRIER

EDWARD B. BIGELOW, M.D.
Assistant Bacteriologist, Board of Health
WORCESTER, MASS.

This epidemic of typhoid fever, which occurred among the customers of one milk distributor, is reported, that once more the probable danger to the community of a carrier of infection, engaged in the production of a food, may be emphasized, and the value of the agglutination reaction of Widal, as a means for locating such a carrier, be more fully appreciated. By reports of such epidemics the public will be aroused to the dangerous possibilities of these carriers. With this realization, the cooperation of whole communities, which is lacking at present, will be enlisted, the selfish personal motives and prejudices of ignorance, which attempt to block the efforts of the health service, will be overcome and the culmination will be a general demand that methods be devised and means be generously provided that such carriers may be sought out in advance, and such epidemics thus anticipated.

In the last twenty-five years, an average of 106 cases of typhoid fever has been reported yearly to the Board of Health of Worcester, a city with a population of 145,000 at present. This is, roughly, an average of one case a thousand of population a year for this period. In fact, however, the city has more than doubled in population in these twenty-five years, while the aggregate number of cases of typhoid fever is actually less in the second half of this period than in the first, increasing this ratio markedly. In the year 1910, the records of the health board show 295 reported cases, more than one case to each five hundred of population. The source of infection in 204 of these cases can be traced to one milk distributor's route. Through misunderstandings between responsible parties because of a change in physicians or transfer to the hospitals, nine additional cases were discovered after the epidemic was over, no report of which had been made to the Board of Health, and this number rightfully should be added to these 204 cases. Thus, in this epidemic at least 213 cases with ten deaths may be certainly attributed to one milk route. If the source of infection in several other cases could be surely traced, it is probable that several more of the 295 reported cases would be enumerated in this epidemic. Of these 213 cases, more than 180, after careful study, may be classed as primary, and it may be said that their infection was incurred at practically the same time. The remainder for the larger part were cases developing in families secondarily to one of the primary cases. Two were nurses employed in the hospitals in the care of primary cases, and a few are to be attributed probably to two cases among the employees of the distributor, who will be mentioned later.

From Jan. 1 to Aug. 11, 1910, only eighteen cases of typhoid fever had been reported to the Board of Health. During that day (August 11) seven more cases were reported. Six of these were on one milk distributor's route. An investigation of the premises of this distributor was made the following morning. Two of his employees complained that for the past two or three days they had had head and back aches, loss of appetite, felt weak and tired, but had continued about their work of distributing milk, washing bottles and other utensils used in the distribution of the milk. On physical examination, both had rose spots and temperatures, the higher only 100.5°. Blood examination showed positive Widal agglutination reactions in both. They were at once removed to the hospital. Specimens of blood and examination of all other persons on the premises were negative in results. These two cases of typhoid fever were not the source of the infection of the six cases reported on the day previously, as their symptoms were synchronous or even later in onset. It was concluded, however, that their infection was incurred from the same source. Therefore, evidently a prior source for the common origin of the infection had of necessity to be sought.

This distributing milk man secured his supply from a milk car and four dairies within a few miles of the city. From the milk car several other distributors also obtained their supply. No cases had developed on their routes. This fact seemed temporarily to rule out the car and its supply as the source of infection. That afternoon the four dairies were investigated. On ordinary inspection there was nothing suspicious about them. No person living on any of these farms, so far as could be learned, was or had been recently sick, with the exception of one woman, who, it was definitely proved before the day was over, did not have typhoid fever. That evening the specimens of blood obtained from every person connected with these dairies—men, women and children—were examined by the agglutination test for typhoid. Of these twenty-five or more specimens one gave a positive Widal test.

This man of the positive Widal was visited again the next day, and his previous history more carefully taken. He had been producing milk for thirty years. He said that he had had typhoid fever twenty-six years ago. For years he had not been sick enough to be confined to the bed. Two weeks before, however, he recalled that for a few days he had had a slight attack of diarrhea with some headache, accompanied by a small amount of bright blood in the bowel movements. He had not given this any especial attention, because he had been subject for years to such attacks, together with bleeding from hemorrhoids. He daily assisted his hired man with the milking and handled the utensils. He boarded in a family of nine, none of whom had had typhoid recently. Their Widals were all negative.

Subsequently (August 19-26), specimens of urine and feces were obtained from this man on four different occasions over a period of eight days. These were examined after the method described by the Overlanders, Graham and Dailey,[1] oxbile, malachite green and Endo's fuchsin agar media being used. The stools were negative as to typhoid. From each of the four specimens of urine, one or more actively motile bacilli was isolated. These bacilli did not stain by Gram's method, did not produce gas in dextrose agar, nor curdle milk, but did produce, however, a slight initial acidity in litmus milk followed by a return to the original reaction the same as did the control. There was no production of indol in peptone solution and no liquefaction of gelatin in seven days. These organisms were agglutinated in a few minutes by a dilution of 1-200 of blood-serum obtained from three different known typhoid patients. At this time, I was undergoing a course of inoculations with typhoid vaccines; my blood-serum also completely agglutinated them in the same dilution in fifteen minutes.

More than two months later (October 31-November 4), this man's blood and urine were again examined. The blood in a dilution of 1-200 gave a positive agglutination reaction with typhoid organisms in less than one-half hour. The three specimens of urine collected on alternate days and plated on Endo gave an abundant growth of only one type of colony. More than seventy of these colonies having been picked off, it was found that each one reacted similarly to the tests previously enumerated. In addition, at Professor M. J. Rosenau's suggestion, a rabbit was repeatedly inoculated during a three-week period with a vaccine made from one of these organisms. The serum of this rabbit at the end of that time gave a macroscopic agglutination reaction when tried out in series against cultures of the laboratory typhoid organism in a dilution as high as 1-1100. The serum of a second rabbit, employed as control and similarly treated with vaccine from the stock laboratory typhoid organism, agglutinated one of these organisms isolated from the urine in a dilution of 1-1350. This was as high a dilution as that in which the stock laboratory typhoid organism itself in the control series was agglutinated by the serum of this second rabbit.

The plates of this last examination were in marked contrast, presenting an entirely different condition of affairs from that which was found when, this same technic having been employed the preceding year, an examination was made of the urine and feces of twelve convalescent typhoid fever patients from the wards of the Worcester City Hospital, the bacteriologic work of both years having been performed in the laboratory of that institution. These twelve patients had been free from fever for from ten days to two weeks or more when examined. A typhoid organism was recovered from three, a positive result of 25 per cent. for the twelve cases. However, out of more than five hundred organisms isolated from these twelve cases, only three proved to be typhoid organisms — that is, only one typhoid organism was isolated in each of the three cases which were positive, while in this carrier case every one of the numerous colonies on the plates apparently was a typhoid colony.

The agglutination reaction seems of much value in tracing the source of milk-borne epidemics of typhoid fever, to judge not only from the experience just cited, where it was most instrumental in bringing this case of a carrier to light, but also from that of the preceding summer in two epidemics of fortunately a markedly smaller number of cases. The probable proof of the source of these two epidemics was not as certainly established by actual attempted isolation of the organism as in this epidemic just reported. The cooperation of the suspected individuals was lacking in submitting to further tests than a Widal, for their hostility was aroused because of the fear that their private interests would be jeopardized.

In the first of these epidemics eight cases occurred on one milk route. On the dairy farm suspected as the source was a case later diagnosed as typhoid fever, synchronous in symptoms with these eight cases, and therefore not the source of their infection. The people living on the farm were questioned, and it was discovered that one young man who had never had any severe illness in his life, had had, some two or three weeks previously, an attack of so-called "grippe" of about two weeks' duration, during which time he had felt unable to attend to his business. For two of those days he had had an attack which he called "cholera morbus." His blood gave a positive Widal reaction.

To the second of these epidemics at least fourteen cases of typhoid fever on one milk distributor's route can be attributed. In the search for a source of infection more than fifty Widals were performed on specimens of blood obtained from all the persons living on the different dairy farms supplying this distributor. Only *one of these Widals was positive.* The *man from whom this specimen was obtained gave no history of any recent illness.* The evidence that he might be the *probable source was strengthened* by this fact: the milk from this one of the several dairies was the milk bottled for the more particular customers, and on further analysis of the cases it was found that it was among those consuming this bottled milk that the fourteen cases occurred.

---

[1] Overlander, C. L. and J. E., Graham and Dailey: Boston Med. and Surg. Jour., Jan. 14, 1909, clx, No. 2, p. 38.

It has been remarked that the light cases of typhoid fever, unrecognized as such, and the carriers of the specific organism constitute the most formidable source of infection in a community possessing a pure water-supply. Each epidemic leaves its residue of chronic carriers, *that are a threat of future epidemics.* These carriers should be sought out and prohibited from engaging in such an occupation as cooking, baking, dairy work, etc., which may from the articles handled and consumed without further cooking endanger the lives of others. Milk, from its nature, is an especially fine culture medium; if contaminated with typhoid bacilli, particularly in the warm summer months, it is a most "effective" intermediary agent from the carrier to the consumer.

The recommendation of the committee of the American Public Health Association on typhoid fever that physicians should be impressed with the necessity of reporting this disease promptly is an excellent one. For, "until the physician, who is really the scout of the public health service, reports the location of the enemy, all our paraphernalia with all its elaborate organization is at a standstill."[2] The truth of this statement is shown by the epidemic reported in this paper, since the Board of Health had no inkling that such an epidemic was about to burst on the community until physicians reported actual cases, when the two employees as secondary sources of further infection were promptly recognized and removed. But these light cases, for which physi*cians are not called in*, and carriers, because they are *unrecognized* as such, are the real danger of initiating idemics.

oid fever has been called a preventable disease, consider it as such is certainly the goal which the health *service must strive to attain.* That man ntly harbors the specific organism of typhoid fever erally recognized at present. Precautions are to protect the public from typical cases. If the chronic carriers of this disease could be known, and the food and water-supplies, as intermediate bearers, be protected from their contamination, typhoid fever could soon be stamped out. The disease is preventable only by working along this line. Therefore, the new and serious problem that confronts the health service at present is, *How is this knowledge of a carrier,* which is of such recent recognition, to be gained, before it is bought at the extravagant price of an epidemic? A *method of defense for this new problem, that is in the* least satisfactory, has not as yet been advised.

The various methods advocated for the discovery of carriers, as general examination of excreta, or even only the examination of the excreta of those persons with a history of a previous typhoid infection, are propositions too large to be practicable. The second suggestion makes no allowance for the fact that in many cases of typhoid carriers there is a lack of a previous history of typhoid fever, and again that many carriers excrete the bacilli only intermittently.

From the experience of the last two years as set forth in this paper, the suggestion is made that specimens of blood for Widals be taken generally from persons living on dairy farms or handling foods that are consumed without further cooking, and then that the excreta of those only that give a positive agglutination reaction be examined. The Widal reaction in most cases of typhoid fever rapidly disappears after defervescence. The presence of post-typhoid suppuration somewhat increases its persistence.[3] Most carriers possess it. Therefore, if a *Widal reaction persists,* that person if employed as mentioned above should be looked on with suspicion until proved free from typhoid organisms by repeated examinations of excreta.

This procedure also is an immense proposition, when, as is the case in the city of Worcester with a population of 145,000 for an example, milk is supplied from more than 600 dairies and 900 stores and distributors. These statistics take no account of bakers, cooks and other persons who come in intimate contact with other kinds of food. This simple procedure of a Widal reaction, however, should certainly be carried out on the blood of all persons handling, or living on farms producing, milk which is put on *the market as certified.*

THE TRYPTOPHAN TEST FOR CANCER OF THE STOMACH WITH SPECIAL REFERENCE TO PEPTIDOLYTIC ENZYME IN THE SALIVA *

J. W. WEINSTEIN, M.D.
NEW YORK

INTRODUCTION

The attention of the medical profession has recently been drawn to new ways of diagnosing cancer of the stomach by means of tests for the simplest products of protein digestion. Emerson,[1] who was among the first investigators to approach this field, found that "cancer tissue contains a ferment which, in the thermostat as well as in the stomach, is able to digest proteins beyond the peptone ('albumose') stage." He also observed that "this ferment is active in the presence of *free* hydrochloric acid." Emerson's discovery, coupled with the well-known fact that pepsin does not, in the stomach, conduct the cleavage of proteins beyond the stage of peptones, offered a method of determining whether or not the stomach has been invaded by a cancerous growth. A test for cancerous enzyme, if based on Emerson's findings, could not be applied, however, with the ease and directness which is desirable in clinical work.

THE GLYCYLTRYPTOPHAN TEST[2]

About two years ago Neubauer and Fischer[3] published a new test for cancer of the stomach, which was based on this same principle, but was applied specifically to the detection of an enzyme having the power of digesting a simple peptid. The substrate selected for this test was glycyltryptophan, a synthetic dipeptid containing the molecular radicals of glycin and tryptophan. Glycyltryptophan is readily hydrolyzed into these two amino-acids. Neubauer and Fischer selected glycyltryptophan as the peptid substrate for their test because tryptophan, which can readily be produced from it by enzymolysis, is the amino-acid that may be detected in the easiest and most direct manner.

[1] Emerson: Deutsch. Arch. f. klin. Med., 1901-02, lxxii, 415.

[2] In this paper the phrase "glycyltryptophan test" is invariably employed to indicate the Neubauer and Fischer process, which includes the use of glycyltryptophan. The term "tryptophan test" will be used to s method, which does not involve the use see Weinstein, J. W.: The Journal A. M. A 5.

[3] Neubauer Arch. f. klin. Med., 1909, xcvii, 499.

In the test, as recommended by Neubauer and Fischer, glycyltryptophan is added to a sample of the stomach contents in question and the mixture is incubated for twenty-four hours. The presence or absence of peptidolytic enzyme is then ascertained by determining with the aid of bromin water, whether or not tryptophan has been produced. A positive result which, according to Neubauer and Fischer, could not occur through the action of anything in normal gastric juice or contents, indicates the presence of a peptidolytic enzyme and implies the occurrence of carcinoma of the stomach, whereas, according to the same authors, a negative result indicates the non-occurrence of carcinoma. Neubauer and Fischer supported their conclusions as to the significance of this test with a series of convincing clinical observations. Naturally, this new test for cancer of the stomach promptly received a great deal of attention and interest.

THE TRYPTOPHAN TEST

I recently published[2] the results of some experiments which showed that the use of glycyltryptophan is superfluous for the detection of tryptophan-producing enzyme in gastric contents. A gastric cancer secretes enzyme which is capable of hydrating proteins into tryptophan and other amino-acids. Gastric contents always contain proteoses and peptones that are readily convertible by cancer enzyme into their corresponding simpler peptids and amino-acids, including tryptophan.[4] Consequently, it is unnecessary to add either a specific protein, or a simple peptid, or glycyltryptophan, as a tryptophan-yielding substrate for the easy detection of cancer protease in stomach contents.[4] It was shown by me that plain stomach contents served more satisfactorily for this purpose than stomach contents mixed with glycyltryptophan.

Previous observers, among them Erdman and Winternitz,[5] Glaesner,[6] and Volhard,[7] employed stomach contents directly for a similar purpose, but as incubation was not a part of the process in any of their methods, their observations as well as their findings, have little practical bearing on the method which was recommended in my original paper.

WARFIELD'S STUDY OF THE ACTION OF SALIVA ON GLYCYLTRYPTOPHAN

There has been wide difference of opinion regarding the value of the glycyltryptophan test for gastric carcinoma. A few have commended it highly, but a large majority have pronounced it valueless. The main objection which has been raised against the test is that glycyltryptophan yields tryptophan in a large number of cases in which no cancer exists, as shown at autopsy and by operation. It has been asserted that most achylia gastrica cases, whether due to carcinoma or not, give a positive reaction with glycyltryptophan.

Warfield[8] has lately made observations which help us to understand the current differences of opinion regarding the value of the glycyltryptophan test.[9] Warfield has found that the saliva of some people, when not acid (to litmus) to begin with, is capable of decomposing glycyltryptophan into glycin and tryptophan. He concluded that *swallowed alkaline saliva*, when mixed with neutral or faintly acid gastric liquid, imparts to the latter the power of producing tryptophan from glycyltryptophan, thus rendering "the *glycyltryptophan test* of no value in the diagnosis of cancer of the stomach." Warfield has shown that the peptidolytic enzyme in saliva is destroyed by heat.[10]

THE AUTHOR'S CONFIRMATION OF WARFIELD'S RESULTS

I have verified Warfield's findings. Every specimen of saliva, except one, in a total of eight was found to exert marked peptidolytic power on glycyltryptophan within twenty-four hours. The experiments in this connection were performed with glycyltryptophan and saliva directly, as a simple mixture, *and also after their mixture with stomach contents, which had either been neutralized or which contained a slight proportion of acid.* Neutralization in these cases was effected with one of the following alkalies: calcined magnesia; sodium bicarbonate and sodium hydroxid (1 per cent. solution).

No attempt was made to ascertain the limit of acidity within which saliva is able to induce the production of tryptophan from glycyltryptophan. Warfield states that acidity greater than that of a 0.05 per cent. hydrochloric acid solution prevents such action.

THE SPECIAL SIGNIFICANCE OF WARFIELD'S FINDINGS

The important facts which have been disclosed by Warfield explain in part the past difficulties with the glycyltryptophan test. That they render its positive responses particularly unreliable in cancer diagnosis is obvious, for such results may be due to swallowed saliva. On the other hand, that Warfield's findings do not disqualify my tryptophan test for cancer of the stomach is equally clear, since the salivary protease does not produce tryptophan from the proteins in non-cancerous gastric contents.

All investigators of the subject agree on the proposition that cancer secretes enzyme which is capable of converting protein into amino-acids. The tryptophan test has all the advantages and none of the disadvantages of the glycyltryptophan test. Warfield's peptidolytic salivary enzyme is devoid of effect on the tryptophan test. I have repeatedly added saliva to normal stomach contents of different degrees of acidity, but have never been able to detect tryptophan, even after prolonged incubation of the mixtures. In one special instance a specimen of stomach contents that contained no *free* hydrochloric acid, and which had been carefully neutralized with sodium hydroxid, (1 per cent. solution), *was mixed with saliva and kept in a thermostat for fourteen days.* Not a trace of tryptophan could be detected in the mixture at any time during the period. A few protocols, in this and other connections, are appended:

---

[4] It is not very likely that stomach contents ever contain mixtures of proteins which would wholly fail to yield tryptophan among the products of complete proteolysis. Gastric mucus yields tryptophan under such conditions. Casein, egg albumin, gliadin and practically all other ordinary food proteins yield tryptophan in comparatively large proportions. It is probable that the proportion of tryptophan which is produced from the proteins in stomach contents, under favorable conditions for the test, is sufficient for detection in all cases except those characterized by practical absence of peptidolytic enzyme. But in such instances glycyltryptophan would also fail to yield detectable proportions of tryptophan. Whether the tryptophan that arises from proteins in stomach contents (in the tryptophan test) is ever decomposed, and sufficiently reduced in quantity (through the continued action of the enzyme), to yield a negative result with bromin water cannot be decided at present. Thus far, however, all observations indicate that no uncertainty is introduced into the test in this way.

[6] Glaesner: Berl. klin. Wchnschr., 1903, xl, 599.

[7] Volhard: München. med. Wchnschr., 1903, l, 2129.

[8] Warfield: Bull. Johns Hopkins Hosp., 1911, xxii, 150.

[9] In referring to "the stages in the complete digestion of coagulable proteins" Warfield states that metaproteins are "commonly called albumoses." It is evident that in this case *albumoses* is a misprint for "albuminates."

[10] Dr. Gies, although suggesting the probability of ereptic and tryptic excretion by the salivary glands, thinks it possible also that the tryptophan-producing enzyme in mixed saliva is derived in part from bacteria in the mouth, especially from cavities in carious teeth. He has planned to investigate these possibilities.

Mrs. S. N., suffering from chronic gastritis, has been coming to my service at the Vanderbilt Clinic for the past nine years to get hydrochloric acid, which does her good. Examination of stomach contents shows: Free hydrochloric acid, none; combined acid, none; total acidity, 4; reaction to litmus, faintly acid.

GLYCYLTRYPTOPHAN TESTS (I-III)

I. Stomach contents, 20 c.c.
Saliva, 10 c.c.
Glycyltryptophan, 1 c.c.[11]
=Marked tryptophan reaction in twenty-four hours.

II. Stomach contents, 20 c.c.
Saliva (previously *boiled*), 10 c.c.
Glycyltroptophan, 1 c.c.
=Marked tryptophan reaction within twenty-four hours.[12]

III. Stomach contents, 20 c.c.
Water, 10 c.c.
Glycyltroptophan, 1 c.c.
=Tryptophan reaction; not so marked, however, as before, in twenty-four hours.[12]

TRYPTOPHAN TEST (IV)

IV. Stomach contents (neutralized with NaOH), 28 c.c.
Saliva, 20 c.c.
Glycyltryptophan, *None.*
Toluol, a few drops.
=No tryptophan reaction.[13]

The effect of saliva on Witte peptone has been tried in experiments of a similar nature—such as are outlined below:

TRYPTOPHAN TESTS (A-B)

A. Witte peptone, 2 gm.
Saliva (Jacob's), 10 c.c.
Water, 20 c.c.
Incubation, 7 days (with toluol).
=No tryptophan reaction.

B. Witte peptone, 2 gm.
Saliva (Kraus's), 10 c.c.
Water, 20 c.c.
Incubation, 7 days (with toluol).
=No tryptophan reaction.

THE AUTHOR'S FURTHER EXPERIENCE WITH THE TRYPTOPHAN TEST

I have been employing the tryptophan test for over a year and have found it a valuable sign in the diagnosis of cancer of the stomach. The main objection to the Neubauer and Fischer test is the frequent occurrence of positive responses in non-carcinomatous contents. This is not the case with the tryptophan test. On the contrary, in the case of the tryptophan test, *negative* responses have occurred in some specimens of stomach contents from true cancerous cases. By means of the tryptophan test I was able recently to distinguish all the malignant from the benign states in a series of pyloric obstruction cases prior to operation. Everybody knows the unusual difficulties that beset the endeavor to make a differential diagnosis of malignant from benign obstruction of the pylorus, since all the clinical features are the same in both conditions.

I am confident that the tryptophan test outranks every other available laboratory means for the diagnosis of cancer of the stomach. Further investigation is necessary, however, before it can be said that one or two positive tryptophan findings in stomach contents absolutely prove the existence of carcinoma. This degree of uncertainty is much less, however, than that connected with any other "sign of cancer." Among the "other signs" are absence of free hydrochloric acid from stomach contents, presence of lactic acid in stomach contents, occurrence of occult blood in stomach contents or feces, stasis of food, and the results of such newer methods as the Solomon, meiostagmin and hemolytic tests. Free hydrochloric acid is absent from stomach contents not only in gastric cancer, but also in chronic gastritis, pernicious anemia, exophthalmic goiter and achylia gastrica. On the other hand cancer of the stomach, chiefly of the pyloric region, may be accompanied by normal and even hyperacid states of the contents. Lactic acid, an important sign, frequently fails to occur in the contents of the stomach in cancerous cases, and it is occasionally present in undoubted cases of chronic gastritis. In general, lactic acid is prone to occur when free hydrochloric acid is absent and especially, also, when the motor powers of the stomach are impaired. Boas-Oppler bacilli are an excellent diagnostic feature of carcinoma ventriculi, but only when present in large numbers. Unfortunately they appear only when the invasion of the stomach by the carcinoma is extensive. They are never present unless free hydrochloric acid is absent and, in general, are not of very common occurrence. Occult blood in stomach contents and in feces occurs in ulcer of the gastro-intestinal tract, cirrhosis of the liver, and also in cardiac and renal cases that are attended by congestion of the viscera. The Solomon, meiostagmin and hemolytic tests are positive in conditions other than carcinoma.

I have made hundreds of applications of the tryptophan test to stomach contents. I have never obtained a positive response in any *undoubted* non-cancerous case, except such as resulted from gastro-enterostomy, in which the resultant artificial conditions favored the flow of intestinal contents into the stomach and thus caused the hydrolysis of the proteins into amino-acids by intestinal protease.

Whether the occurrence of tryptophan in the gastric contents affords an early sign of cancer, I cannot say. Thus far I have not diagnosed a case in its early stages by means of the tryptophan test. I have had several cases, however, in which the first sign of cancer of the stomach was a positive response in the tryptophan test —all other signs failing to give a clear indication. I have lately had an elderly patient (Mrs. O. R.), who suffered from digestive disturbances accompanied by low gastric acidity. Her nutrition and general condition were such as to preclude the diagnosis of carcinoma, and I thought I was dealing with a case of chronic gastritis. The tryptophan reaction, however, was repeatedly positive. Four to five weeks later a tumor appeared in the region of the stomach, which grew very rapidly. The case was then diagnosed by every one who saw the patient as an undoubted case of cancer of the stomach. Operation was proposed, but the patient disappeared from observation.

---

[11] This quantity of glycyltryptophan solution is the volume provided by Kalle & Co. (Biebrich am Rhein) for a single test in accord with the directions of Neubauer and Fischer. The volume is usually a little greater, though it is seldom more than 1.5 c.c. The exact concentration of the solution is unknown to me.

[12] This positive result was due undoubtedly to the enzyme which had been introduced into the gastric contents in the saliva *swallowed* by the patient.

[13] This mixture was kept in a thermostat for seven days, but no trace of tryptophan could be detected at any time during that period.

Another experience of mine related to an elderly man (N. F.) who presented himself to my service at the Vanderbilt Clinic with stomach trouble. I obtained several positive tryptophan tests and on the strength of these only, as the other features did not clearly indicate malignancy, I advised an operation. This was refused by the patient, who disappeared from observation. Three months later I traced him to Mount Sinai Hospital. There an exploratory laparatomy was performed and a lymphosarcoma of the middle of the stomach was found and resected.

ANOMALOUS EXPERIENCES WITH THE TRYPTOPHAN TEST

In numerous applications of the tryptophan test I have had anomalous experiences with several cases. The stomach contents of one patient (Case 16 of my original paper), a man of 54 with a suspicious history of carcinoma, gave repeated tryptophan tests in the presence of free hydrochloric acid. The patient felt well afterwards for a couple of months, when I lost track of him for a time. Lately, however, I have had the opportunity of again examining him. He is now in good health and apparently free from cancer of the stomach.

Another anomalous case was that of a middle-aged woman, who had a typical pyloric obstruction, with marked peristaltic movements and gastrectasia. The tryptophan test was repeatedly positive. The patient refused an operation. Four months later she seemed to be somewhat improved, but still had all the stigmata of pyloric obstruction. At that time two tryptophan tests applied to different specimens of gastric contents were negative. This patient is now in the hands of a colleague who thinks that her pyloric obstruction is a benign one, because it shows no signs of further increase. We should not forget, however, that a scirrhous carcinoma is of slow growth and that, with a very small open passage through the pylorus, and lavage, the patient may hold her own for a long time.

Another case of interest in this connection was that of Mrs. L. S., aged 64, who presented a typical history of cancer of the stomach, such as sudden onset of illness of nine months' duration, loss of appetite, considerable loss of flesh and strength, vomiting, and vomiting of coffee grounds. Occult blood was found repeatedly in the stomach contents and feces. An exploratory laparotomy was performed by Dr. A. A. Berg, who failed to find any abdominal lesion. In this case repeated tryptophan tests were negative. Once, however, it was strongly positive, but in that instance the contents had been rendered very faintly alkaline with magnesium oxid, and the resultant proteolysis was undoubtedly due to intestinal protease. It was intended, in this procedure, to enhance, if possible, the action of the cancer enzyme through alkalization, an expedient which, as was found, may possibly lead to error.

Dr. Berg performed a pylorectomy on another patient, Mrs. S., whose history and findings pointed strongly to the diagnosis of cancer of the stomach. Several tryptophan tests were positive. The pathologic report was "inflammatory," and not malignant.

DISADVANTAGES OF THE TRYPTOPHAN TEST

The tryptophan test is inconstant. Tryptophan may appear in the contents from one meal and fail to appear in the contents from the next. This implies inconstancy in the secretion of the carcinoma enzyme, but it does not indicate variability in the reactive tendencies of the reagent in the test. I saw in consultation about three months ago an old lady who had all the stigmata of cancer of the stomach (no palpable tumor, however), and I failed to get a positive tryptophan test in a specimen of stomach contents. Only one test was tried in this case. As a rule, however, several tests of different specimens of gastric contents yield a positive reaction in each case of cancer.

SOURCES OF ERROR IN APPLYING THE TRYPTOPHAN TEST

There appears to be one important source of error in the tryptophan test, and that is regurgitated intestinal fluid. Boas[14] was the first to obtain duodenal contents from the stomach. He massaged the duodenum toward the stomach and obtained a variable quantity of bile-stained fluid through a stomach tube. Later Boldyreff,[15] at the instigation of Pawlow, introduced olive oil into the stomach through a tube and subsequently extracted the contents. Olive oil has the double effect of checking gastric secretion and stimulating pancreatic secretion. It also acts as a lubricant, and back flow of intestinal contents is facilitated. By such means, duodenal contents may be secured. This line of work was taken up by a good many investigators, such as Faubel,[16] Volhard,[17] Molnar,[18] Ohrl and Schittenhelm[19] and their experiences coincide in the fact that some duodenal secretion may be secured in this manner. The observations of Ohrl and Schittenhelm indicate that under ordinary conditions spontaneous regurgitation of intestinal contents into the stomach takes place. In considering, however, the degree to which the tryptophan test may be vitiated by erepsin or trypsin, or both, we must not forget that these enzymes are destroyed by the acid of gastric contents. Moreover, I have repeatedly kept non-cancerous stomach contents, devoid of free hydrochloric acid, in a thermostat at 40 C. for days and even weeks, without obtaining a positive response in the tryptophan test. It is obviously necessary, however, in every serious application of the tryptophan test, to prevent all possible regurgitation of duodenal contents. To prevent this occurrence the stomach contents should be withdrawn gently, and also without any straining on the part of the patient. For this purpose the aspiration method instead of the expression process should be employed. A tube with thin walls and a bore not more than 10 mm. in diameter (30 French) should be selected for the purpose. The patient should be instructed to breathe continuously during the extraction. The manipulation should be conducted by one who is skilled in the work and not by an untrained assistant. By disregarding these rules, by letting the patient press forcibly on the tube until he gets blue in the face, some intestinal regurgitation will probably result and may vitiate the test. Vomitus is not reliable for obvious reasons. If, in spite of all these precautions, one obtains a specimen of stomach contents with a greenish color, and which gives the chemical tests for bile, the specimen should be discarded and another one secured.

Various authors have stated from time to time that occult blood vitiates the glycyltryptophan test. They might also presume that it vitiates the tryptophan test. In my original paper I discussed these improbabilities. I have not ignored the fact that blood contains proteases. I am certain, however, that blood, even when present (in the tryptophan test) in a quantity sufficient to impart a distinct red tinge to the contents, is not able to produce tryptophan in detectable proportion. I have repeatedly studied this matter, from various points of view, and have always obtained negative tests for tryptophan in contents to which moderate amounts of blood had been added—in one case even after incubation of the mixture for seven days. I have also obtained negative tryptophan results in such mixtures of glycyltryptophan and blood, even after incubation for the same length of time. Of course, it is likely that the addition of large quantities of blood would effect hydrolysis of associated protein, but in such cases the tryptophan test could not be carried out, for it would be impossible to discern the characteristic red color resulting from the addition of the bromin.

The presence of *free* hydrochloric acid does not necessarily interfere with the test. I have found tryptophan in several instances of carcinoma with high gastric acidities.

TECHNIC OF THE TRYPTOPHAN TEST

The Test Meal.—The ordinary Ewald test breakfast is not suited to the test. This has been shown repeatedly. A simple and effective test meal is a glass of water, hot or cold and very sweet, with some white bread, or toast or biscuits. Milk may also be added. The contents are extracted in about one hour. A regular dinner with extraction after two to four hours, also serves the purpose. Any substance that is likely to impart color to the contents, such as strong tea, coffee, strawberries, tomatoes, etc., should be excluded from the test meal. After their extraction a portion of the contents should be *filtered* and tested directly for tryptophan. If the test is positive, no further treatment is necessary. If the direct test is negative, however, the contents, filtered or unfiltered and without the addition of toluol or other preservative, should be kept in a thermostat for from twenty-four to forty-eight hours, and then tested again for tryptophan. The addition of a preservative appears to be superfluous, for I have shown repeatedly that the bacteria which develop do not produce tryptophan in a detectable proportion.[20] The tryptophan test may often be obtained in positive cases without incubation, by merely keeping the contents at room temperature for from twenty-four to forty-eight hours. Incubation, however, is preferable.

The Test for Tryptophan with Bromin Water.—In completing the tryptophan test, *filtered* stomach contents should be employed. A volume equal to 6 or 7 c.c. is satisfactory for the purpose. This volume in a test-tube is treated with a few drops of a 3 per cent. acetic acid solution and then saturated aqueous solution of bromin is added, drop by drop, from a pipette. The appearance of a reddish-violet or rose-red color shows the presence of tryptophan. If, after the addition of about 4 drops of bromin water, the expected color does not appear, the mixture should be allowed to stand for about fifteen or twenty minutes, when the characteristic color may develop. If, by the end of that time, the rose color fails to show, then more bromin water should be slowly added, drop by drop, until the mixture becomes yellow or until a rose-red color is imparted. If a reddish color is produced, the mixture should be allowed to stand again, when the tinge may grow deeper. Considerable practice is required for the accurate performance of the test in the presence of very minute proportions of tryptophan, because a slight excess of bromin may make the characteristic color indistinguishable. Excess of bromin imparts a lemon-yellow color to the mixture. Whenever the reddish color merges into a yellow we know positively that there is an excess of bromin in the mixture. The opening at the tip of the pipette from which the bromin solution is dropped should be a very small one. The bromin water should invariably be added drop by drop, and the mixture should be well shaken after each addition.

Bromin itself should be handled with great care, for it is extremely irritating to the respiratory mucous membrane. Under no circumstance should plain liquid bromin be mixed with the gastric contents to be tested. An aqueous bromin solution may be kept saturated by retaining in it a slight excess of the heavy liquid bromin.

Acetic acid is added to the mixture to be tested, because the reaction appears at its best in an acid medium. Alkali, by combining with the bromin, prevents the reaction with tryptophan. Almost all stomach contents are acid and in testing them for tryptophan the addition of acetic acid may not be necessary. In mixtures of very low acidity, however, the addition of acetic acid is especially desirable.

I wish, in conclusion, to express my indebtedness to Prof. William J. Gies for the use of his laboratories and suggestions in my work.[21]

71 East Ninety-Sixth Street.

THE TREATMENT OF HEMOPTYSIS IN PULMONARY TUBERCULOSIS *

MAX ROTHSCHILD, M.D.
SAN FRANCISCO

Two months ago I read a paper on the treatment of hemoptysis in tuberculosis before the meeting of the Medical Society of the State of California, at Santa Barbara. When I returned from the meeting, I was notified on my arrival in San Francisco that a dozen of my patients were having hemorrhages. The peculiar feature of this fact was that they all started to bleed at about the same time, which can be explained only by changes in atmospheric pressure. A number of these patients bled for only one or two days, and showed no alarming symptoms, but two of them continued to bleed severely, and in spite of all the usually employed means and manipulations the hemorrhages did not stop.

I shall give in detail the history of one of these patients, because this one case will be sufficient to explain the soundness of the method I have used for the last two years in treating severe and dangerous hemorrhages. All other cases are more or less alike, and their description would be only a repetition in slightly varied form.

---

[20] I cannot say that this would always be the case, for some bacteria and fungi that I have not thus far encountered may be able to produce *detectable proportions* of tryptophan under the conditions of the test.

[21] The following, together with references numbered 2, 3, 8 and 19, constitute a complete bibliography of the glycyltryptophan and tryptophan tests to the time of writing this paper.

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, *at the* Sixty-Second Annual Session, held at Los Angeles, June, 1911.

History.—The patient in question is a young man of 18 years, from Stockholm. He went to Turban's sanatorium in Davos about two and one-half years ago, on account of tuberculosis of the left upper lobe. During his stay there the right lung also became involved, but after nineteen months' treatment he was discharged, as all the symptoms had subsided. He returned to Sweden, then came to California to spend the winter of 1910-11.

Examination.—The patient came to my office in February, 1911. Two weeks before he had caught cold and had had some sputum which was examined, and tubercle bacilli in abundance were found. The evening before he came to my office, he had had a hemorrhage. Examination showed increased resistance over the left upper lobe, with sharp scar breathing. In the back of the left lung, between scapula and vertebræ, there was pronounced crepitation during inhalation and exhalation over an area the size of a dollar. There was harsh bronchovesicular breathing over the right upper and middle lobe, with small and medium sized moist and dry râles. The spot in the right lung had again become active.

Treatment and Course.—The patient went to our sanatorium in Belmont, and during February, March and April he was under the usual treatment. The last examination (April 6) showed no change in the breathing over the left lung. The right lung had improved considerably. There were only a few râles in the second intercostal space. There was sharp breathing in the right upper lobe during inhalation and exhalation, and exhalation was prolonged. The patient had gained from 15 to 20 pounds, and was looking and feeling fine. His temperature was normal; the cough had diminished; there were no night sweats; and the sputum was about one-tenth the amount which he had had on entrance, but there were still from 6 to 8 tubercle bacilli to the field. He was allowed to get up for a little while every day and to take moderate exercise. In the night of April 21 he had a severe hemorrhage, and another the following morning. As he complained of pain in the right lung, my assistant strapped that side tightly. He believed that the hemorrhage came from the right lung, but could not examine the patient at the time on account of the danger of renewed hemorrhage. The patient was given gelatin, calcium chlorid, ice-bags, etc., but that night he had another hemorrhage. The temperature rose to 101.5-102. He was given very slight doses of opiates, just enough to keep the cough under control. We tried to examine him on the morning of April 23; there were medium and large râles over the right as well as over the left lung. It was impossible to find out definitely from which side the hemorrhages came, but we had the impression that it was from the right side. That night he had a hemorrhage, another the following morning, and again the next morning. We examined him again, and again were unable to tell with certainty the spot from which the hemorrhages came. As soon as the boy tried to breathe a little deeper, he would have a hemorrhage. We had an *x*-ray taken by Dr. Freytag, from which it was evident that the right lung was a good deal more involved than the left, and as this harmonized with our findings, and the hemorrhages recurred regularly every twelve or twenty-four hours, we decided to compress the right lung. On the morning of April 27 we produced an artificial pneumothorax on the right side. We let about 600 c.c. of nitrogen run in, and from that moment the hemorrhages stopped. At the second inflation, two days afterward, we found about 2 cm. negative pressure. We again let 600 c.c. of nitrogen run in, which produced about 2 cm. positive pressure. Since that time the patient has been treated in the usual way, the artificial pneumothorax has been kept up, and so far there has not been a particle of blood in the sputum.

This case is in my opinion a most interesting one and teaches us a great deal.

To summarize: A young man, tuberculous for two years, has acute hemorrhages which are not only very intense, but also obstinate. All the usual methods of treatment are without effect; the temperature is gradually going up to 102; the patient is not only frightened to death, but is becoming weaker daily; and the hemorrhages show no tendency to cease. The artificial pneumothorax stops the hemorrhages instantly; the temperature goes down; and the patient begins to improve. (Unfortunately, this patient died of miliary tuberculosis a few days ago, but that has no bearing on the phase of his sickness under discussion.) Besides this case, I have treated seventeen others during the last two years, all with just as severe and obstinately recurring hemorrhages.

It is needless to state that in cases in which there was blood in the sputum only occasionally, or in which there were decided hemorrhages without any serious aspect, or without a tendency to recur too frequently, I have confined myself to the usual old remedies or manipulations, which are too well known to necessitate an enumeration. Only when these different remedies seemed to have no effect, or when the hemoptyses had a serious aspect on account of their intensity, have I used the artificial pneumothorax. I have chosen only such cases, not because I thought that the operation might be harmful in lighter ones, but merely because I did not want to feel, in publishing these first cases, that our old remedies might have done the work just as well.

It is advisable to discuss here to some extent the indications and contra-indications for artificial pneumothorax.

Forlanini himself gives the following as the indications:

1. In uncomplicated cases of one-sided phthisis with slow or subacute course and with free pleura, without regard to the degree of the lesion.
2. In cases in which adhesions exist, if these adhesions can be removed by artificial pneumothorax.
3. In cases of double-sided phthisis which do not show an acute course, and in which the lesions in both sides are not far advanced.

Karewski,[1] in his paper discussing the newer methods of surgical treatment of tuberculosis of the lungs, speaks well of the artificial pneumothorax. He says, however, that it is indicated only when all physical and dietetic means have been exhausted, and that it is absolutely contra-indicated when the other lung is involved. The autopsies of patients who were treated with artificial pneumothorax, but who died in spite of its use, showed that the clinically observed improvements corresponded with the post-mortem findings. In the lung which was artificially compressed were found a large amount of interstitial tissue and indications of scar formation; only a very few fresh tubercles were found, and these contained a surprisingly large amount of dry, cheesy degeneration, showing *in toto* signs of a reparative process. He also found that in the clinical picture of properly selected cases, the weight of the patient increased and the general condition improved considerably; he noticed a decrease in the number of bacilli, and a disappearance of the elastic tissue in the sputum, which itself became less and often disappeared entirely.

I should like to divide the indications for the operation into different groups.

1. Those which might be called safe indications: Severe one-sided involvement, with a healthy other side, and no adhesions, or only fresh ones, on the diseased side.

---

[1] Karewski: Ztschr. f. Tuberk., xiv, No. 6, 1909, p. 465-479.

2. Permissible indications: (A) Severe one-sided involvement, with fresh or not too old adhesions on the other side. (B) Severe involvement of one side; slight involvement of the other, not including more than one-third of the lung, and without cavity formation. Involvement of the upper lobe on the better side gives the more encouraging outlook. (C) Severe involvement of one side, with adhesions, and obstinate hemorrhages with or without adhesions.

3. Dubious indications: Severe involvement of one side and cavity formation in the lower lobe of the other lung.

4. Contra-indications: (A) Extensive involvement, with cavity formation in the better side. (B) Thick and firm adhesions all over the side on which the pneumothorax should be made. (C) Severe complications of other organs.

A tuberculous larynx can only be favorably affected by the pneumothorax, as less sputum will pass the larynx.

There are also many cases of diarrhea in tuberculosis, in which this complication is not a result of organic tuberculosis of the intestines, but only represents the attempt of the body to secrete the poisons. The diarrhea can disappear after this secretion of poisons has been removed by artificial pneumothorax.

One of the most important works which has been published on artificial pneumothorax is that of Brauer and Spengler.[2] It gives a report of 102 cases, each case described in detailed, and afterward shortly and exactly discussed.

These men have not confined themselves to the narrow indications given by Karewski or by Forlanini, and their results are surprisingly good. I mention this fact especially, as one might say that the cases of hemoptysis are few in which artificial pneumothorax should be used. This is not true. Naturally, the ideal cases are those in which only one side is affected, and the other side is entirely healthy, but we do not see many of these.

In the great majority of cases the other side is slightly affected, and this fact is no contra-indication. On the contrary, many writers on the subject agree that the slightly affected side shows an improvement while the badly diseased side is compressed. I want to mention again that I am not discussing the pros and cons of the artificial pneumothorax in the treatment of tuberculosis, but only in the treatment of one symptom, i. e., hemoptysis; and that I am especially discussing this method in cases of severe hemorrhages in which all usual remedies have failed. In such cases I should not hesitate to produce an artificial pneumothorax; but—and this is an important point—I should not keep the bleeding side compressed for any length of time if the other side showed a decided progress of the disease. After the first inflation the nitrogen becomes absorbed rather *quickly; usually in twenty-four hours* the pressure, which was positive or neutral just after the operation, is again negative. If the hemorrhages have stopped, and if the general condition of the patient is not good, I should not reinflate. In other words, one must be guided by clinical observation in each case; and if the physician has his eyes open, and notices every change in his patient, there is no real danger connected with this method.

CLIMATE IN THE TREATMENT OF PULMONARY TUBERCULOSIS *

W. JARVIS BARLOW, A.B., M.D.
LOS ANGELES

It is to be expected that men who live in health resorts would make some special study of climatic influence on diseases, and through experience of many years reach some definite opinion of the effects due to climate. It is well known that the physicians of the southwest have decided views in favor of climatic treatment with their own special brand, and I make no apologies for being classed as one of them. Space does not permit, nor is it my intention to give explanations and descriptions of the factors, atmospheric conditions, and the principal types of climate, or descriptions of different health resorts; all of which may be read in recent publications under my signature. It would seem better to give the indications and contra-indications for climatic treatment of tuberculosis and to give the classes of cases suitable for this type of climate.

Climatic treatment must deal not alone with the factors or atmospheric conditions of climate, such as temperature, humidity, sunshine, pressure, etc., but also with others quite as important, the non-climatic features, i. e., temperament of the individual, financial resources, stage of the disease, individual characteristics, etc. With these considerations in view, the essential thing in selecting suitable climate is to individualize all cases. Since the search to find specific climate for tuberculosis is *apparently at an end*, we must remember always that the place which has suited one case may be entirely unfit for the next, and that each patient must necessarily be separately studied in connection with the non-climatic features of a place.

All fresh-air and open-air treatment is a part of the climatic treatment and is now being used in each part of the country, in every kind of climate, for all diseases, especially all chronic diseases, so that a change to meet the right conditions for open-air treatment in any climate is sufficient proof of the value of such treatment. No hospital ward to-day is complete without its open-air balcony or adjacent porch, and patients are being placed out of doors in every climate in all but the worst weather. With the proper use of this treatment, pneumonia has lost much of its terror and some eastern physicians using it say they have saved many lives that formerly would have seemed beyond help. It is Nature's way of bringing about benefit or a cure, and, fortunately, the use of it for the cure of tuberculosis has shown us how inexcusably it has been neglected in the treatment of other chronic diseases.

If we acknowledge then, that climatic treatment is a great factor in our care of the tuberculous, is it not reasonable to suppose that the place suited to the individual, where he can obtain the best climatic factors would give better results than his own home where the atmospheric conditions are not so favorable?

What then are the atmospheric conditions of greatest importance? They are:

1. Plenty of air.
2. Percentage of sunshine.
3. Amount of humidity.
4. Temperature with its variations.
5. Pressure of air.
6. Severity of winds, dust, etc.

---

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

Certainly the pure air and abundance of sunshine must be accepted as a help for every case. With regard to humidity and temperature, whether the climate chosen should be dry or moist, cool or warm, it must depend on the non-climatic factors, or the individual considered. Certainly for the majority of cases that climate which is dry and cool is to be preferred. As to the pressure of air, also, whether the case should be in high, medium or low altitude, depends on other factors than those of climate alone. Careful consideration must be given to the individual, the age, temperament and the stage of the disease. Further, climatic change should not be made until the patient has been under treatment at home sufficiently long to have him understand the details of the open-air cure, the dietetics and hygienic management of tuberculous cases, and until the physician in charge has familiarized himself with the resort selected that the patient may obtain the right accommodations and the best medical care. It is absolute folly to send any patient who needs attention to a climatic resort unless the home physician has assured himself that the patient will have as good medical care as at home. Experience of several years in a health resort has taught me that many lives are sacrificed through this omission, and by rough and improper handling of sensitive, peculiar temperaments, which class of patients are too often set adrift. Unless climatic treatment can be properly carried out, it is far better to keep the patient at home under right management, because it is conceded by all that many tuberculous patients will recover in any climate under the sun.

For a general rule to be specialized with exceptions given later in the paper, I would state that patients with pulmonary tuberculosis developing between the ages of 17 and 40 should be sent to a high, dry altitude. When disease has begun after the age of 40 years, patients should be kept in lower altitudes, in climates more equable and relaxing; some patients show greater improvement near the coast where sunshine and equability are features. Children will do better always at or near the coast in either cold or warm climates.

INDICATIONS AND CONTRA-INDICATIONS FOR HIGH-ALTITUDE TREATMENT

The great mass of tuberculous patients under the age of 40 years, early tuberculosis with or without fever and constitutional symptoms, including patients with hemoptyses, and those with beginning destruction, present indications for high-altitude treatment (3,000 to 7,000 feet). So also do cases with compensated cardiac disease and with no great degree of emphysema.

Contra-indications are presented by acute pneumonic cases with high fever, rapid pulse and respiration, advanced cases with extensive involvement or cavity formation of both lungs, with extensive adhesions and dyspnea, chronic fibroid cases which have a good deal of bronchitis and emphysema, young children and infants, and many patients of a neurasthenic type, or nervous temperament.

In selecting high altitude, limitation in this paper is made to those resorts in the United States with which I am familiar as it will be impossible in this short time to mention all the resorts that are available. Patients demanding high-altitude treatment for the whole year should be sent to the Rocky Mountain region, the chief resorts of which are to be found in Colorado, New Mexico and a few in Arizona. All of these resorts show similar characteristics, Colorado leading in accommodations, care and medical attention, New Mexico being somewhat superior in its climatic advantages. The winters are cold and stimulating, the summers cool and bracing. They have the natural advantages for the treatment of pulmonary tuberculosis; pure air, dryness, abundance of sunshine, altitude, a wide difference of temperature between day and night.

The chief resorts of Colorado are, of course, Denver (altitude 5,200 feet) and Colorado Springs (altitude 6,198 feet), with their outlying districts. No better places than these may be found for the treatment and care of pulmonary tuberculosis, and nowhere else are climatic features that will agree with so many patients. They may be compared favorably with the famous resorts of Switzerland. The chief objections to not a few patients are the sharp diurnal changes and the cold of winter. For such patients my plan has been to recommend the lower elevations of Arizona and California for the winter months and to have the patients return to Colorado for the other six or eight months. As before stated, each case must be separately studied that one may know what influence cold or warm temperature has on the individual. Higher elevations in Colorado, such as Manitou (altitude 6,300 feet), Glenwood Springs (altitude 5,200 feet), and Estes Park (altitude 7,000 feet) are changes that are made for the summer season.

The New Mexico resorts are always to be considered for high altitude treatment, remembering that the winters and summers there are both slightly warmer than in Colorado and for this reason may often be more suitable. The atmosphere is sufficiently dry to make the heat of summer at any of the resorts never uncomfortable or oppressive and the nights are always cool. When more accommodations and comforts are provided, the resorts of New Mexico will be second to none. Santa Fe (altitude 7,013 feet), Las Vegas (altitude 6,500 feet) and Albuquerque (altitude 5,200 feet) are the three resorts in the northern part of the state with a climate not unlike that of Denver. The cold is not quite so great nor the summer temperature so high, with the exception of Las Vegas. Of the three places, Santa Fe has the best summer climate. The principal resort in the southern part of the state is Silver City (altitude 6,000 feet), which has become well known for its climatic advantages and can be safely recommended for high-altitude treatment at any time of the year. The summers are never too hot nor the winters too cold and of all the southwest region it has no superior. Patients who have lost ground at other places have often made surprising gains in this region. Fort Bayard (altitude 6,200 feet) is not far from Silver City and has been chosen by the government as offering the best climatic conditions of our states.

Arizona is limited in its high altitude resorts, only one of which, Prescott (altitude 5,260 feet), can safely be recommended for pulmonary cases. It has all the advantages of the Rocky Mountain region except that the winters are milder and warmer, which may be an advantage. It is well protected from severe wind and dust storms. Flagstaff (altitude 7,000 feet) has perhaps the best all-year-round climate in Arizona, but no provision has yet been made for invalids, though it has every natural advantage.

Southern California has places of high altitude with natural and excellent climatic features in the valleys of the San Jacinto and the San Bernardino Mountains, but these places cannot be recommended, as there is no provision made for the treatment of patients with pulmonary cases. These mountain places, as well as those of the northern part of the state, are more or less well equipped for summer tourists and those who no longer need medical attention.

For medium-altitude treatment (1,000 to 3,000 feet), there are many resorts throughout the east which are available and suitable for the whole year. There are the Adirondack Mountains of New York represented by its many lake resorts so well known that they need no exploitation here. Saranac Lake stands as no other one place for its great representation in the out-door treatment of pulmonary tuberculosis, and no man in the profession is more loved than the one who made this region famous. Besides the Adirondacks, the east has the Catskill Mountains, the White Mountains, resorts of New Hampshire, the Blue Ridge Mountain region of Pennsylvania, and the several resorts of Virginia. In the south, however, none stand so well to-day as Ashville (altitude 2,255 feet), which has gained an enviable reputation. There is no better place for all-year-round residence for those who need this altitude. The air is tonic and stimulating like that of higher elevations. In the west we have only two important places of medium altitude, Phoenix (altitude 1,087 feet) and Tucson (altitude 2,400 feet). I place all the resorts of Southern California in the low altitude group. Both Phoenix and Tucson are suitable only for the winter months, both having distinct advantages for dryness, amount of sunshine and the mildness of the winter climate. Tucson on account of its altitude and more stimulating climate has an advantage over Phoenix, and experience has taught me that Tucson will suit more cases than will Phoenix when climate alone is considered. For those who can exercise and ride about the country, Phoenix will be more agreeable.

Low-altitude resorts are to be found for different months of the year in almost every section of the United States. In the east are the places along the lake region, the Great Lakes, the Thousand Islands, Central Plateau of Massachusetts, the Berkshire Hills, northern New Jersey, etc. In the south are the resorts of North and South Carolina and Georgia including, of course, Aiken, Augusta and Thomasville, each having their advantages for the winter months and all more or less relaxing in type. In the west, we have San Antonio, Texas, (altitude 680 feet), which can be safely recommended for the winter months (December to April). Near the Pacific coast in California a great valley has recently been made comfortable and many find health under these dry, equable conditions. I refer to the Imperial Valley. Banning and Palm Springs, Cal., are similar resorts of a desert type cut off from the humidity and rain storms of the Pacific Coast.

The low-altitude types of Southern California are chiefly situated in the San Gabriel Valley which extends from Redlands (altitude 1,200 feet) to Pasadena (altitude 800 feet). Along this valley are growing towns and outlying districts which have been built up chiefly by health seekers: Redlands, San Bernardino, Riverside, Ontario, Pomona, Duarte, Monrovia, Sierra Madre, Altadena and Pasadena. The best winter climate of this group and the one offering the best accommodations for tuberculous cases is found at Redlands, Riverside, Monrovia and Sierra Madre. Redlands, Riverside and Ontario are too warm in summer for most invalids, but the other places reaching from Monrovia down through Pasadena and to the coast are suitable for all-year-round residence with some hot days in summer when the temperature reaches 100 F., but the relative dryness always saves any great discomfort. Many invalids reside in these localities, especially the tuberculous who need low altitude treatment under equable conditions. Here are found the climatic advantages of pure air, abundance of sunshine, equable temperature and a few hours of dryness each day. Part of the twenty-four hours throughout most of the year in southern California is moist. Fogs are numerous in the spring and summer months for a part of many days, extending many miles over the inland places, usually 30 and often 50, and disappearing earlier the greater the distance from the ocean. The days of summer without these fogs are the hot, dry days; this is especially so for the inland resorts.

The chief charm of southern California is the great amount of sun through the greater part of the year, its equability, the foliage and vegetation, the out-door life possible for everyone and the sedative or relaxing effect produced, a paradise for children and old people and those handicapped by ill health.

People 40 years of age with pulmonary trouble or children with any tuberculous lesion do better in southern California near the coast or in her low altitude resorts than do young adults. The latter class, except those contra-indicated, should be sent to a high, dry altitude where the air is more stimulating and where the cold and changes of temperature usually act favorably.

It is hard to think that anyone should believe that there is no therapeutic value in climate. Dr. Hinsdale in a recent publication has emphasized the value of climatic treatment. He sent a question to the deans of medical colleges in several of our large cities. "What would you do for yourself, climatically, if you were told for the first time that you had incipient pulmonary tuberculosis?" All the answers were in favor of climatic treatment under the direction of a man who understood the disease. If such a question were put to you to-day what would your answer be?

Fifth and Spring Streets.

THE USE OF HYPODERMICS OF CITRATE OF IRON IN THE SECONDARY ANEMIA OF TUBERCULOSIS *

E. S. BULLOCK, M.D.
Physician-in-Chief to the New Mexico Cottage Sanatorium
AND L. S. PETERS, M.D.
Associate Physician New Mexico Cottage Sanatorium
SILVER CITY, N. MEX.

Some years ago, Dr. B. R. Shurly, of Detroit, urged on me the importance of using citrate of iron hypodermically in the secondary anemia of tuberculosis. Shortly before, it had been his privilege to visit Italy, where he became acquainted with the common practice of Italian physicians of using iron in this manner, and the very great success of the method as applied to almost all secondary anemias.

As all understand, a high altitude is in itself very efficient in the removal of the secondary anemia of tuberculosis, and, therefore, I began the use of iron hypodermically tentatively and only in those cases in which the anemia proved resistant to dietetic, hygienic treatment, plus residence in a high altitude. Thus, it may be seen that I have confined its use to the most unfavorable class of patients, furnishing a most rigid test of the usefulness of the method.

Employing the hemoglobin content as an index of the degree of secondary anemia, as well as an actual erythrocyte count, I found that the hypodermic use of the citrate of iron permitted me to control the anemia with

---

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

almost mathematical precision, and that it actually in no single instance failed to improve the quality of the blood to at least some degree in the 256 cases in which we had employed it. I would like to emphasize that over 70 per cent. of these cases are in the advanced and far advanced classes, in which the anemia is a commonly manifested phenomenon, and in which we have the right to expect the least from any remedial measure.

I found it to be uniformly successful in raising the hemoglobin standard to normal in all cases in which the patient might be considered to be doing well, or in which the status quo was seemingly maintained; that in most cases it required but thirty or forty consecutive daily doses to accomplish the ideal of such medication, and, as before stated, in no instance whatever did it fail to be efficient, at least in some degree.

As time went on and I became impressed with the scientific exactness of the method, its employment was made a routine procedure in all cases in which there was a reduction of 10 per cent. or more in the hemoglobin content. This was done for the purpose of removing as quickly as possible at least one of the manifestations of tuberculous toxemia, without awaiting the considerably slower restoration of the blood which follows the combination of high altitude and sanatorium treatment. During the past five years there has been a slight improvement in our results in the treatment of all classes of pulmonary invalids. As we have changed our methods in no other particular, I feel safe in attributing the improvement to the hypodermic use of iron.

In a paper before the National Association for the Study and Prevention of Tuberculosis, at the recent Denver meeting, my associate, Dr. L. S. Peters and myself, presented the tabulated statistics of our use of iron. I would refer those interested in the actual facts on which this paper is based, to our joint presentation of the subject before the Denver meeting. Heretofore, I have referred only to the use of citrate of iron in doses of 0.05 gm. for the sole purpose of removing secondary anemia. We, however, in practice employ a number of formulas in which the citrate of iron is combined with metarsenate of soda, strychnin, glycerophosphates, etc., the purpose being to utilize the alterative tonics of demonstrative value. We have not found it necessary to use a larger dose of citrate of iron than .05 gm. Others, who have used larger doses, have observed sudden vomiting to follow its administration.

The technic of the method is to employ the ordinary hypodermic syringe and needle, selecting the buttock as the least inconvenient site of injection, and giving an injection daily until the result is obtained.

Under ordinary conditions, I would not consider it necessary to explain the source of the iron we employ. Having recommended this method to a great many physicians, however, we have received many complaints of marked irritation at the site of injection, sometimes continuing for hours, where in our experience we have never witnessed this phenomenon, and patients complain so little of the subjective sensations following injections that they will often voluntarily request a so-called course of iron for its general tonic effect. On inquiry we have discovered that those instances in which local irritation followed the injection, some of the American preparations of iron had been employed. It seems, therefore, that this paper would be wholly incomplete without mentioning the fact that we obtained these preparations from the Italian pharmaceutical houses, as they have been much more successful in manufacturing preparations free from irritating local effects.

ABSTRACT OF DISCUSSION

ON PAPERS BY DRS. ROTHSCHILD, BARLOW AND BULLOCK

Dr. William C. Voorsanger, San Francisco: Dr. Rothschild has quoted Brauer and Spengler in their report of 102 patients treated by artificial pneumothorax. I have studied their monograph very carefully, and I did not get the impression that their results were uniformly good. In their work they draw no conclusions. They simply give the indications for producing nitrogen compression of the lung, and the results therefrom, some of which were fairly good, but many were negative. They only reported one case of hemoptysis treated in this manner, and this patient died two weeks after the compression had been made. Dr. Rothschild certainly deserves great credit for pioneering artificial pneumothorax in this part of the country, and unquestionably this method should be attempted in those cases in which the hemorrhages cannot be stopped by any other means, and in which the tuberculosis can be with certainty diagnosed as limited to one lung, or in which the case is absolutely hopeless and we must try some therapeutic measure.

I agree with Dr. Barlow in the statements he has made. His remarks concerning the patient living in a climate best adapted to his condition should impress us, but I would go still further and insist that a patient with tuberculosis should remain in the climate where he has received his cure. I have seen patients who have been cured or improved in Arizona or southern California, come back to northern California and break down very rapidly. Only recently I was called to see a patient who had been home one week from southern California, discharged as cured. Although he lived in a very lovely bungalow in the Piedmont hills, and carried out all the instructions he had received in the south, he was taken with a very severe hemoptysis. It lasted five days, and the patient's condition at the present time is none too promising. This is only one illustration of how a patient suddenly changing climate may suffer bad results.

Dr. John W. Foss, Phoenix, Ariz.: Dr. Rothschild's paper is most interesting, yet from personal observation I would advise against placing too much confidence in this proceeding. As a lost resort I would most certainly advise its use after the results described by Dr. Rothschild. I have seen at post mortem a case in which the lung had been compressed with nitrogen gas for some time, yet the hemorrhage which produced death was from the lung so compressed. The length of time of compression may have been a factor in this instance. Dr. Barlow's advice that both physician and patient should familiarize themselves with conditions of life in the open air of the western country is exceedingly valuable. It is the exception to find an eastern physician who understands the conditions to which he sends his patient in the west. Any physician in the southwest would be glad to give his fellow practitioner any information he may wish. Mayor Alexander at the general meeting very forcibly brought out the fact that many patients, particularly tuberculous patients, are sent into the West for the benefit of their health without means and without a knowledge of existing conditions. This is positively cruel, not only to the patient, but it is placing an unreasonable expense on the people of the West. For instance, Maricopa County, Arizona, spends at least $12,000 a year for the care and support of indigent patients sent there by physicians and friends of the patients who do not understand the conditions under which they must live. Every patient should have sufficient resources to be able to expend at least $1,000 yearly for his living and personal expenses. Dr. Barlow states that all tuberculous patients between the ages of 17 and 40 years should go to a high, dry climate. I will agree with him that they should go to a dry climate with a high percentage of sunshine, but I positively disagree with him that they should all go to a high altitude, especially when they can be sent to a dry climate at a moderate altitude. As Dr. Voorsanger says, the patient suffering from tuberculosis should be cured at as nearly as possible the same altitude as that in which he wishes to make his future home. If he wishes to live in a high altitude, then he should go to the mountains, but if he wishes to live at a moderate or low altitude he should go to that resort where he can have the benefit of dry, pure air and a maximum of sunshine. At Phoenix the humidity averages the lowest of any place in this country. It has a high percentage of sunshine; the average wind movement is 4.7 miles per hour for the year; the annual rainfall is only 6.7 inches; the sensible temperature or wet-bulb thermometer rarely goes above 72 degrees in the summer and the altitude is only 1,080 feet. No place in the world presents so nearly an ideal condition for the recovery of the tuberculous patient who wishes to make his future home at a low altitude at the minimum risk of reinfection or relapse.

Dr. James W. Laws, Lincoln, N. M.: Eight or nine years ago I had occasion to use, by means of the Murphy apparatus, nitrogen gas compression of the lung in pulmonary hemorrhage in a number of cases. As with other remedies for pulmonary hemorrhage, in many cases the result seemed marvelous, while in other cases pleuritic adhesions prevented compression of the lung, and where the adhesions were torn loose harm resulted. It is difficult to know from which lung the bleeding comes, but a knowledge of the physical examination and clinical symptoms of the patient before the hemorrhage, along with what can be ascertained at the time of the hemorrhage, usually enables one to form an idea which lung is bleeding and whether compression of the lung is indicated or not. When sufficient vesicular breathing space is left over the other lung, after compression of the bleeding lung, and in cases in which there is reason to believe the bleeding comes from a congested area of recent infection, and in cases in which there are recurrences of bleeding from day to day, sapping the vitality of the patient and not controlled by ordinary measures, I believe that the compression of the bleeding lung by nitrogen gas is a valuable remedy.

Dr. Max Rothschild, San Francisco: Artificial pneumothorax should be used with caution. But it is always possible, if one should inflate the wrong side, to deflate again. It is just as easy to take out gas by means of a bottle with a vacuum as it is to take out fluid after a pleuritic exudation. It has been asserted that the results of Brauer and Spengler are not uniformly favorable. This assertion seems to overlook the fact that many of their cases appeared to be pretty nearly hopeless from the start; and even some of these patients were cured by artificial pneumothorax. If Brauer and Spengler consider the artificial pneumothorax contra-indicated in hemoptysis, I can only say that I do not agree with them. The indication in severe cases of hemoptysis is a most logical one. In Brauer and Spengler's publication of 102 cases, I found only one of hemoptysis, and this was a hopeless case in which the patient died about two weeks after the hemorrhage. As far as I remember, this is the only case in which Brauer or Spengler advocated pneumothorax on account of the hemoptysis, which stopped promptly after the pneumothorax was made. The patient died, not as a result of the pneumothorax, but of the tuberculosis which was far advanced at the time of the operation. Dr. Foss is correct when he says that a hemorrhage from the compressed lung is possible, because it stands to reason that a diseased lung is so tightly adherent to the chest wall that a complete compression is not possible. But if a complete compression is possible, there does not exist any logical reason why a hemorrhage of the lung should not stop just as a bleeding blood-vessel would stop under compression during a surgical operation.

Dr. W. Jarvis Barlow, Los Angeles: Patients should have no climatic change unless they can be put under as good medical attention as at home. The statement is correct that individuals even then should not go unless one is sure to whom one is sending them and what the patient will do. If one is sure that the patient will do as he is told, then he should have climatic treatment. Otherwise they will get into the hands of somebody who will set them adrift, as so often happens here in our southern country. Dr. Voorsanger spoke of the return of the disease if the patient returned to his home. That is true. He should stay until he has immunity or cure and then he is able to live elsewhere. The treatment consists in individualizing the patient. There are patients who gain benefit but not an arrest. I think often patients go away from the place where they have made that arrest too early. In regard to Dr. Foss' criticism of my statement in regard to altitude, I expected that would be challenged. That young people should be in high, dry altitudes, I know is true. Of course they might do well in a climate of low altitude, but many need the stimulating effect of the high altitude. After 40 I do not think altitude is so important.

THE DIETETIC MANAGEMENT OF PELLAGRA

GEORGE M. NILES, M.D.
ATLANTA, GA.

While the etiology of this malady is by no means settled, most observers agree that in its major manifestations it is a gastro-intestinal disease, and since it is such, curative measures for the irritation of this tract, combined with supportive measures for the upkeep of the body, are of prime importance.

There are some principles in its dietetic management rather differing from that properly accorded to gastro-intestinal disturbances in other disorders, which seem worthy of consideration.

Until the theory is exploded that pellagra is due to some toxic substance in either sound or spoiled corn or corn products, I feel that we are in duty bound to give our patients the benefit of the doubt by excluding such articles from the dietary.

Simply to prohibit this class of foods, without entering into details, is likely to result in misunderstanding with consequent failure. I recently knew of a north Georgia mountaineer, who obediently cut out corn bread and grits, but did not consider it necessary to omit his daily quota of corn whiskey.

Bass, of New Orleans, also reports a female pellagrin who denied ever having eaten corn food of any sort. She had been reared in a section of the country and in a family in which corn was considered good food for horses and hogs, but not for people. It seemed this case was about to disprove the maize theory, when her husband reluctantly admitted that she was in the habit of eating corn starch secretly—a pound or more daily.

That this morbid craving for starch—amylophagia—is not so very uncommon, is shown by the fact that three women, one white and two negroes, observed in the clinic for internal medicine at the Atlanta School of Medicine during the last four months, have acknowledged this habit, though in each instance with evident unwillingness.

Another fact worth mentioning is the adulteration of the cheaper grades of flour with "corn hearts," a custom quite prevalent up to a short time ago. I am informed, however, that, since the pure food laws have been enforced, this adulteration has practically ceased.

Occasionally some case of pellagra is reported, in which there is no apparent evidence that the sufferer has ever eaten any corn products, but I am confident, if the history is thoroughly enough investigated, corn in some form will be found to have entered into the dietary at some time.

Beginning with the earlier gastro-intestinal manifestations, we are generally called on to treat an intermittent and seemingly causeless diarrhea. This early diarrhea I believe to be mainly of central origin, and, to an extent, compensatory. For this reason it is not wise to cut down too greatly the daily amount of food, nor does a very limited dietary seem to exert any marked effect on the disordered bowels.

The patient whose incipient pellagrinous symptoms are recognized is known to be in for a long and taxing siege, and his daily caloric requirements should be guarded most zealously.

The woody vegetables and those yielding a large amount of residue are mechanically contra-indicated at any time diarrhea is present, but care should be exercised that they are replaced by other nourishing articles.

It seems that all along in the course of the disease the flesh proteins are specially well borne, and even in those cases in which there is much active gastro-intestinal irritation, they agree better than in a like amount of irritation from other causes. Tender broiled steak or roast beef may be given once or twice daily, or, if the mouth is too sore to chew, either the scraped beef or that ground in a sausage mill may be given. This also applies to the white meats.

Eggs are generally permissible, though if there is a flatulent tendency, it is well to give only the whites. The albumin of raw eggs may be prepared in various ways, limited only by the ingenuity of the nurse, and I have never known them to set up any trouble.

Sweet milk is valuable when it agrees, but unfortunately many pellagrins show an idiosyncrasy against it. Flatulence frequently follows its ingestion, and in many patients the stomachs furnish enough rennin to coagulate the milk promptly, but are tardy in disintegrating the curds, so there is present a sense of weight and discomfort in the epigastrium. Peptonizing the milk occasionally obviates this, but very few pellagrins relish peptonized milk.

Buttermilk is a most useful article of diet, seldom upsetting the stomach or intestines. It has served me well in so many cases that I can in general recommend it. The artificially soured milk, or lacteal champagne, containing all the fat, is also worth a trial, and is often found highly appetizing.

Where constipation is in evidence, oatmeal, tender vegetables (in puree form), thoroughly baked Irish—not sweet—potatoes, or cereals with but little sugar, will aid the peristalsis of the intestines.

My experience with pellagra has made me chary in the use of alcohol. It would appear that the possible food value of alcohol is more than counterbalanced by its malign effect on the gastro-intestinal mucosa; so, when possible, I omit it entirely from the dietary.

In exceptional cases, when I permit whiskey or brandy, I see that it is well diluted, either as milk punch, eggnog, or with grape juice or lemonade.

Practically the same may be said concerning the alcoholic proprietary food preparations. As an aid to the daily regimen, or to tide over some dietetic emergencies, some of these are useful; but as a dependence to supply bodily caloric requirements, they are a "delusion and a snare." To furnish sufficient calories with these preparations alone would keep the patient in a state of alcoholic coma, plus all the resultant evils reflected on the whole alimentary tract. This is no imaginary picture, I assure my readers; the fact has been impressed on me by some melancholy instances coming under my observation, in which zeal had outstripped discretion, and in which evidences of alcoholic stimulation were thoughtlessly attributed to other causes.

During the whole course of pellagra, the patient should be nourished to the limit of assimilation, and in most instances the gastro-intestinal tract will "stand for" and care for more aliment than when similarly inflamed from other diseases.

The foregoing brief suggestions I trust may be of service, as they are deduced from a considerable number of dietetic experiences in the management of this protean malady; and when the problem of upkeep in pellagra is solved, the outlook for the sufferer is greatly brightened.

IMMUNITY IN TUBERCULOSIS

ITS PRODUCTION IN MONKEYS AND CHILDREN [*]

GERALD BERTRAM WEBB, M.D.
AND
WILLIAM WHITRIDGE WILLIAMS, M.D.
ASSISTED BY A. M. FORSTER, M.D., AND G. BURTON GILBERT, M.D.
COLORADO SPRINGS, COLO.

In former publications[1, 2] we have shown that large numbers of virulent tubercle bacilli may be inoculated into guinea-pigs without producing tuberculosis, provided that very few bacilli are at first inoculated, and that the numbers are increased slowly. In addition, Lieb[3] has shown the possibility of inoculating rabbits with virulent bovine tubercle bacilli in a similar manner.

The work now reported will indicate that monkeys (*Macacus rhesus*), animals which, when kept in captivity are exceedingly vulnerable to tubercle bacilli, can also be safely given increasing amounts of virulent human tubercle bacilli, if inoculated in a manner similar to that in which the animals above referred to were inoculated.

Twelve monkeys (*Macacus rhesus*) were procured and were tested with Old Tuberculin according to Römer's[4] method for cattle. A positive reaction is indicated by at least a 75 per cent. increase in the measurement of the skin-fold.

When we were satisfied that the monkeys were probably not already infected with tuberculosis, we started inoculations with the living virulent human tubercle bacilli, June 8, 1910, and the following plan indicates how each animal was to be treated:

1. Control.
2. 25 bacilli in one dose and no further inoculations.
3. 100 bacilli in one dose and no further inoculations.
4. 200 bacilli in one dose and no further inoculations.
5. Increase slowly, 1, 3, 5, 10, 15, 20 bacilli, etc.
6. Increase slowly.
7. Increase rapidly, 1, 5, 10, 20, 50, 100 bacilli, etc.
8. Increase rapidly.
9. Increase slowly, 5, 10, 15, 20, 25, 30 bacilli, etc.
10. Increase rapidly, 5, 15, 45, 75, 125, 200 bacilli, etc.
11. Control.
12. 50 bacilli at one dose and no further inoculations.

The culture used in the following work was isolated Jan. 19, 1909, by Professor M. A. Barber with the aid of antiformin. The patient, from whom it was isolated, died of pulmonary tuberculosis a few days later.

On account of scarcity of guinea-pigs, we were not able to test the virulence of the culture on guinea-pigs until May 22, 1911. At this time Guinea-pig 1, weight 744 gm., received a subcutaneous inoculation of 35 bacilli; Guinea-pig 2, weight 575 gm., received 75 bacilli; Guinea-pig 3, weight 723 gm., received 125 bacilli.

All these pigs were killed a few weeks later and found to be infected with active tuberculosis.

After five months had elapsed since the previous tuberculin inoculations, the monkeys were again tested by the Römer method.

Two and a half months later, the weekly living bacilli inoculations still being continued, the Römer test was again applied.

It appeared from these tests that Monkeys 8, 10 and 11 must be infected, having given in their skin-fold measurement a percentage increase of 75 and over. The amount 20 mg. was unusually large and was given by mistake. Monkey 11, a control, was now killed and careful search was made for the presence of tuberculosis. Smears were made from the bronchial, mesenteric and inguinal lymph-glands and stained by the Ziehl-Nielsen and Gram methods. No tubercle bacilli could be found. Portions of the glands were macerated and injected into a guinea-pig, Feb. 10, 1911. This pig was tested intradermally, April 9, 1911, with 20 mg. Old Tuberculin. No reaction.

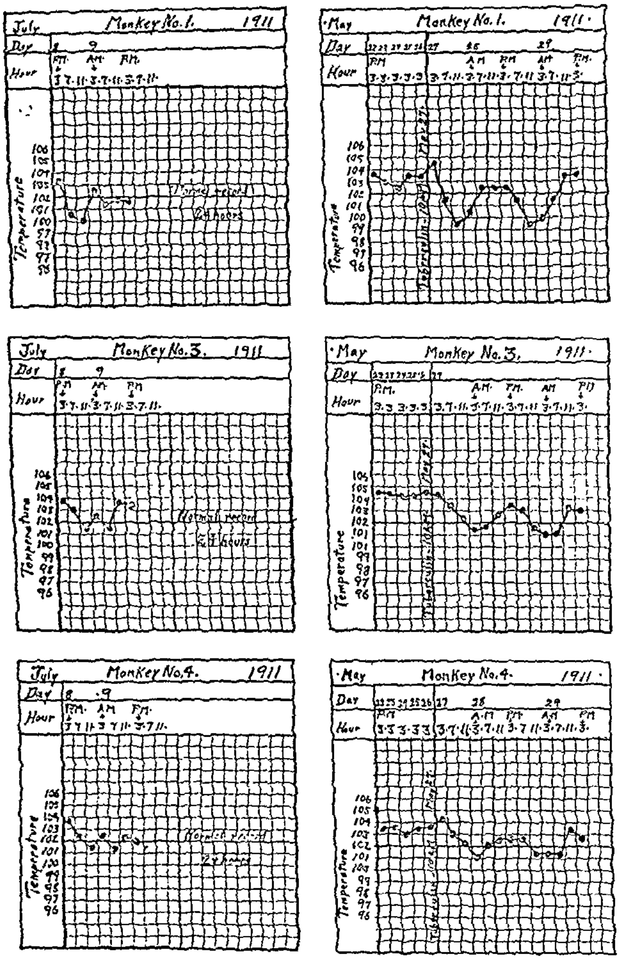

Fig. 1.—Temperature charts for Monkeys 1, 3 and 4.

May 28, 1911, the guinea-pig was killed. Necropsy *showed no evidence of tuberculosis.* From the fact that Monkey 11 was proved to have had no infection with tuberculosis it would seem that the positive intradermal reactions were a result of tuberculoprotein hypersensitiveness. Monkeys 7 and 8 were again tested, May, 1911, with 20 mg. Old Tuberculin intradermally. No reactions followed. The conjunctival test was again applied as follows:

May 25, 1911. One drop of 2 per cent. O. T. (Cutter's) in 9 per cent. sodium chlorid instilled into the right eye of each monkey.

May 26. No change.

May 27. No change.

It was now decided to give the remaining monkeys a subcutaneous injection of 5 mg. Old Tuberculin and to watch the temperatures resulting. The work of White and Fox[5] was carefully followed and the accompanying temperature curves show no increase of temperature following the injection of the tuberculin.

It will be noticed in the table of Monkey 2 that a severe night drop occurred on the second day and the monkey became so ill it was thought he would die. He recovered the next day, but it was decided to kill him and also Monkey 8, which had received such large doses.

TABLE 2.—DATES OF INOCULATIONS AND THE NUMBERS OF BACILLI INOCULATED

Date	Monkeys Nos. 5 and 6 Each No. of bacilli	Monkeys Nos. 7 and 8 Each No. of bacilli	Monkey No. 9 No. of bacilli	Monkey No. 10 No. of bacilli
6/ 8/10	1	1	5	5
6/15/10	3	5	10	15
6/23/10	5	10	15	30
6/30/10	10	20	20	50
7/ 7/10	15	50	25	75
7/14/10	20	125	30	105
7/28/10	30	300	40	150
8/ 4/10	40	450	55	200
8/11/10	50	700	70	250
8/18/10	65	1,000	90	325
9/ 7/10	80	1,500	115	400
9/17/10	100	2,000	140	500
10/ 6/10	125	2,800	175	600
10/15/10	150	4,000	185	700
10/20/10	175	5,500	215	800
10/28/10	200	7,000	250	900
11/ 4/10	225	9,000	300	1,000
11/11/10	250	11,000	350	1,100
11/17/10	275	13,500	400	1,200
11/25/10	300	15,000	450	1,300
12/ 1/10	350	18,000	550	1,500
12/ 8/10	400	21,000	650	1,700
12/15/10	450	25,000	750	2,000
12/22/10	500	30,000	850	2,400
12/29/10	550	35,000	1,000	2,800
1/ 5/11	600	40,000	1,200	3,300
1/12/11	700	50,000	1,500	4,000
1/19/11	800	60,000	1,800	4,800
1/27/11	900	65,000	2,100	5,600
2/ 3/11	1,000		2,400	

The autopsies of these monkeys gave no evidence of tuberculosis. Smears were made from a large number of lymph-nodes and stained by Ziehl-Nielsen and Gram methods. No tubercle bacilli could be found. *Portions of their lungs, lymph-nodes, spleen, liver and kidneys were macerated and injected into guinea-pigs. The guinea-pigs showed no evidence of tuberculous infection at autopsy. Portions of the macerated organs were treated with antiformin, but no tubercle bacilli could be found.*

The feces of each animal were twice examined by the antiformin method for tubercle bacilli; none, however, could be found. The normal night drop of a healthy monkey is well shown in the case of Monkey 1. It will be noticed that some interference with this night drop following the injection of the 5 mg. Old Tuberculin *seems to have occurred in some of the monkeys. This may be due to* the presence of specific antibodies or to tuberculoprotein hypersensitiveness as also the curious effect on Monkey 2 may have been.

---

[5] White and Fox: Observations on Monkeys After Injections of Koch's Old Tuberculin, Tr. VI, Internat. Cong. of Tuberc.

Antibodies in the serums of the monkeys were tested for by means of the meiostagmin reaction described by Ascoli[6] and Izar.[7] This reaction depends on the decrease in surface tension which occurs when the specific antibodies in serum unite with the appropriate antigen when incubated together. The surface tension is accurately measured before and after incubation by means of the stalagmometer of Traube.

We prepared the tubercle antigen from the same culture used in the inoculation of the monkeys, following the direction of Izar and Ascoli.

The monkey serum was obtained in large quantities by dissecting out the jugular vein under chloroform anesthesia.

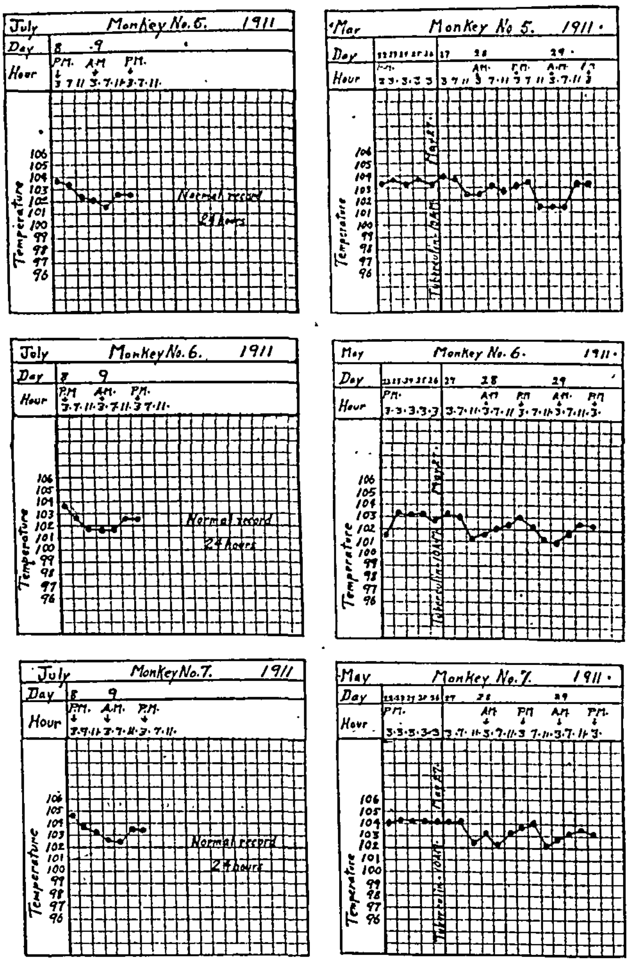

Fig. 2.—Temperature charts for Monkeys 5, 6 and 7.

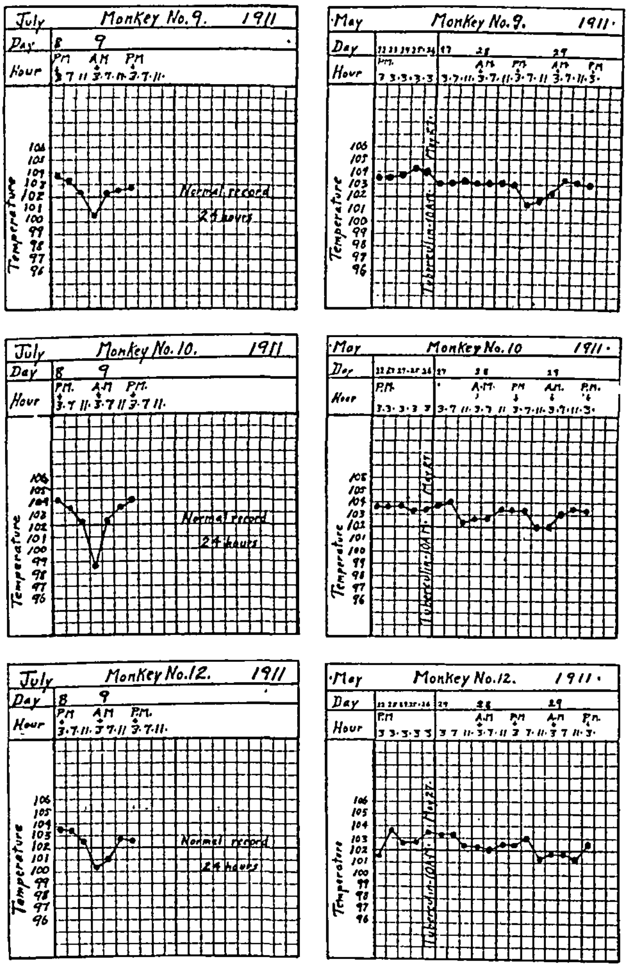

Fig. 3.—Temperature charts for Monkeys 9, 10 and 12.

The serum from Monkey 2 representing an almost normal monkey and the serum from Monkey 8 representing an animal that had received excessively large doses of tubercle bacilli, both gave negative results. The test was applied June, 1911.

Emery's[8] method for measuring quantitatively the specific antibodies in a given serum was also made use of. The test is an application of the Bordet-Gengou phenomenon. When the antibodies combine with the appropriate antigen, complement is extracted and hemolysis prevented. Emery has suggested a means of measuring the time necessary for complete absorption of complement which he terms the absorption time, and he uses it as an index of the amount of antibody present. In general the more antibody present the shorter the absorption time.

For carrying out the test we followed the technic of Emery and used (1) a sterile emulsion of tubercle bacilli in normal saline, from the same culture used in the inoculations; (2) fresh serum collected in a Wright's capsule from the ear of each monkey; (3) an emulsion of sensitized red corpuscles. This consisted of one part washed human corpuscles added to four parts of immune serum. The immune serum was obtained from a rabbit which had been repeatedly injected with well-washed human red corpuscles. The use of the red corpuscles of the monkey for injecting the rabbit would have been better. Our work thus far seems to show that monkey serum has a natural amboceptor for the red corpuscles of some people, so we may avoid the use of rabbits' immune serum in future tests.

Serums from Monkeys 1, 2, 7 and 8 were tested in the manner suggested by Emery and failed to show any complement deviation, the absorption time being prolonged in each instance. The tests were made in June, 1911, after inoculations had ceased.

As yet we have made no attempt to demonstrate other possible antibodies.

[6] Ascoli: The Meiostagmin Reaction, München. med. Wchnschr., Jan. 11, 1910.

[7] Izar: München. med. Wchnschr., April 19, 1910.

[8] Emery: Immunity Reaction in Diagnosis, Lancet, Feb. 25, 1911.

Differential leukocyte counts were made. The total leukocytes of monkeys per c.mm. average about 15,000. The differential counts were made from blood obtained when the animals were fasting.

We have shown[9] that differential leukocyte counts are of some value in indicating the degree of tubercle infection. It will be seen from Tables 4 to 15 that no evidence of infection can be deduced.

Judged by the high percentage of lymphocytes, and also from their dentition, the monkeys were young animals.

It must be remembered that the high percentage of lymphocytes which persist may be due to the altitude.[9]

Two boys, G. R., aged 3 years, and W. R., aged 3 months, were first tested by means of the von Pirquet skin test and both were found to be negative. The father of these boys died a few weeks later of pulmonary tuberculosis and the mother gave evidence of slight tubercle activity in one lung, accompanied by irregular temperature.

The children were inoculated with bacilli from culture B.[2] as indicated by the following figures:

TABLE 18.—NUMBER OF BACILLI INJECTED

Date	No. bacilli	Date	No. bacilli	Date	No. bacilli
10/20/10......	1	11/23/10.	18	12/29/10......	100
10/27/10...	3	12/ 1/10......	25	1/ 5/11......	125
11/ 3/10......	5	12/ 8/10	35	1/12/11......	150
11/10/10......	8	12/15/10.	50		
11/17/10......	12	12/22/10......	75		

Total number bacilli received by each child, 607.

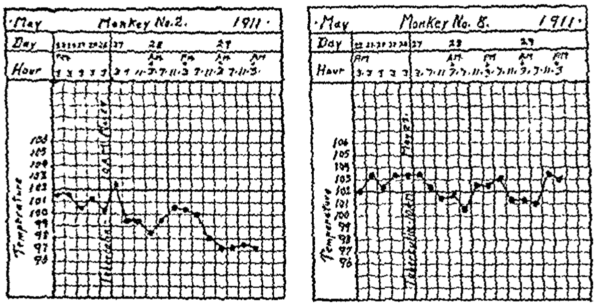

Fig. 4.—Temperature charts for Monkeys 2 and 8.

The children were now again tested by means of the von Pirquet skin test and again the reaction was negative. We realize the intradermal test might have been more thorough, but as our results suggest with this test in monkeys and, as Krause[10] reports, with this test in guinea-pigs that it would seem possible to sensitize to tuberculoprotein, it is perhaps fortunate that we did not employ it. The children have gained weight and are thoroughly healthy to date. May 22, 1911, after four months' freedom from inoculations, the children were again tested and found again to be negative to the von Pirquet reaction.

CONCLUSIONS

1. We have not yet ascertained the exact number of tubercle bacilli of the culture employed which will infect a rhesus monkey.

2. A rhesus monkey, weighing 2,332 gm., withstood infection when injected at one dose with more than six times the dose of human tubercle bacilli which caused tuberculosis in a guinea-pig weighing 744 gm.

3. Two monkeys each received safely virulent human tubercle bacilli enough to kill at least 12,000 full-grown guinea-pigs.

4. No antibodies so far have been satisfactorily demonstrated in the sera of the vaccinated monkeys.

5. The temperature charts indicate the possible presence of such antibodies which might be interfering with the normal night drops following the subcutaneous inoculation of Old Tuberculin for diagnostic purposes.

6. It would appear that it is possible by the intradermal inoculation of Old Tuberculin to sensitize the skin of a monkey to tuberculoprotein.

7. Two children, both of whose parents were tuberculous, have been successfully vaccinated with upwards of 600 virulent human tubercle bacilli, without infection being produced to date.

Our grateful thanks are due J. E. Fuller, A.B., of Colorado College, for a large amount of valuable assistance.

1222 N. Cascade.

ABSTRACT OF DISCUSSION

Dr. J. F. Hultgen, Chicago: Some time ago I was able to show that tuberculosis in its three stages has three different kinds of blood-pictures. In the incipient stage of tuberculosis I have found the two curves, i. e., the polynuclears and mononuclears, close together, and even overlapping. In the second, the toxic stage, we have a definite corresponding anatomicpathologic substratum and a definite blood-picture. In the third stage there is mixed infection, and the total white curve rises with the advance of the disease. Dr. Webb has succeeded in immunizing two persons, who have kept their immunity for months. I think this immunity may extend even further, for this reason: All diseases followed by long immunity have a negative phase lasting a long time; at least that is true in the typhoid fevers. Why those diseases which are followed by long immunity should show this blood-cell production I do not know. Andrews of London has done some work in that direction. He believes that the incubation of typhoid infections is nothing but the extended negative phase of leukopoiesis with the polynuclears screened within the lung capillaries. That, however, has not been confirmed. Dr. Webb is on the right road and immunity from tuberculosis in animals, and presumably in the human, is not only possible but likely. I think he has taken the first step toward establishing a ground on which can be based the immunity from tuberculosis, which kills so few and makes so many sick; whose mortality is so small, and whose morbidity is so great. If a patient dies with tuberculosis, that is not saying that he dies of tuberculosis. As to whether he is in possession of a tuberculous infection is for us to decide, and I think Dr. Webb has made this easy.

Dr. Roy E. Thomas, Phoenix, Ariz.: Dr. Webb says the mononuclears in his monkeys averaged about 70 per cent., and this increase he thought possibly was due to the altitude. Dr. Watkins of Phoenix has recently made some experiments which show that we have there in normal individuals a percentage of leukocytes higher than they have in Colorado Springs. I think that altitude might perhaps fail to explain the high percentage of mononuclears in monkeys at Colorado Springs. Dr. Webb did not infect any of his monkeys. May it not be possible that all of his monkeys were already immune to tuberculosis?

Dr. E. R. Le Count, Chicago: I am reminded by this report of instances in which tuberculosis apparently finds its chief soil in the bones, instances of generalized miliary tuberculosis, with fever and enlarged spleen and outbreaks of tuberculous osteomyelitis in different bones. In some such cases the patient's general health suffers but little and there is an apparent immunity on the part of tissues other than the bones. I do not make this comment to hint at the possibility of bone tuberculosis in the monkeys Dr. Webb examined, but to call attention to the habit, so to speak, that the bacillus has formed in such cases, of growing in bones. The other viewpoint I have already stated in suggesting an immunity for other parts of the body than bones.

[9] Webb and Williams: Some Hæmatological Studies in Tuberculosis, Tr. Nat. Assn. for the Study and Prevention of Tuberc., 5th annual.

[10] Krause: Hypersusceptibility to Tuberculo-protein, Jour. Med. Research, xxiv, No. 2.

Dr. M. P. Ravenel, Madison, Wis.: I had the pleasure of seeing these monkeys and of going over the work with Drs. Webb and Wilson. I am proud of the fact that America can claim credit for the bulk of the work done in the immunization of tuberculosis. While Dr. Webb was not born in this country, he has become an American citizen and it looks as if we were going to get at the root of the matter in America. There are two things in this work which are of interest to me: one is the lack of antibodies, or at least inability to demonstrate them. If we know anything about immunity it is that it depends on the production of antibodies. That is not true always but, generally speaking, we must believe that immunity is due to the production of antibodies. The second point of interest to me is the infection of human beings. We know Behring's theory, that human beings are inoculated with bovine tuberculosis in early life; and Calmette's idea, that those of us who retain our immunity to tuberculosis are those who have had a single large dose, not sufficient to overcome the organism, or repeated small doses so spaced as to allow complete recovery between doses; that those who remain healthy have been vaccinated and have become immune. The question comes up, how much of a dose must a person take to be overcome by tuberculosis? I hope Dr. Webb will further explain the lack of the antibodies.

Dr. Gerald B. Webb, Colorado Springs, Colo.: I take it that the question of altitude would come in in regard to the increased lymphocytes found by Dr. Thomas at Phoenix, for we have found even an altitude of 800 feet gives higher lymphocyte counts than does sea level. I am grateful to Dr. Le Count for mentioning the possible bone infection. It is most important and we will pay more attention to this possibility in the monkeys. I do not believe any tuberculous lesions are present in them anywhere to date. We realize how healthy and vigorous they are when we have to catch them. Replying to Dr. Ravenel's questions concerning antibodies: We have so far failed to demonstrate them unless the interference in the night drop of some of the monkeys following the tuberculin test indicates their presence. In a patient who gets well naturally from diphtheria or even tetanus, antibodies cannot be found in the blood. Antibodies are probably a second line of defense, whereas our inoculations have probably only increased the first line, or the physiologic defense. Our monkeys are now in their second season. They have been kept in small cages in a small room but with the windows open. This room is used for boot-cleaning. Upwards of fifty tuberculous invalids have been in the room at different times and part of the time the monkeys were cared for by a man with advanced pulmonary tuberculosis. As the charts indicate, the lymphocytes of these monkeys still remain high in spite of the monkeys becoming older. This is no doubt the result of the altitude as we have shown to be the case in other animals. As the lymphocyte is considered the natural antagonist of the tubercle bacillus, our work of inoculation with live bacilli has been done under the most favorable conditions on account of the increased numbers of these cells present at this altitude.

The Subhyoid Tug.—Dr. M. L. Graves, Galveston, Texas, writes: The tracheal tugging is often a pronounced and important sign in thoracic aneurysm. It is, however, not so important in recent years, since radiography and other exact methods enable us to diagnose tumors of the chest at an earlier stage and with considerable accuracy. I have observed in a number of patients with thoracic aneurysm with short, thick necks, considerable difficulty in grasping the cricoid cartilage so as to elicit this sign. This is true also in patients with unusual prominence and sternal approach of the sternomastoid muscles, and in some fat necks. Under such circumstances it is comparatively easy to grasp the body of the hyoid bone at its outer and inferior borders and push it up a little and elicit a distinct tug. It is not so strong usually as the cricoid tugging, but is distinct sometimes when the latter is unavailable. It might be designated as the subhyoid tug.

EFFECTS OF HYPODERMIC INJECTION ON THE SECONDARY ANEMIA OF CHRONIC PULMONARY TUBERCULOSIS *

W. JARVIS BARLOW, A.B., M.D.
AND
ROBERT L. CUNNINGHAM, A.B., M.D.
LOS ANGELES

For several years iron preparations have been used hypodermatically in the treatment of secondary, and arsenic in the treatment of pernicious, anemia. In 1908 Peters[1] reported favorable results after two years' use of iron citrate hypodermatically in the treatment of secondary anemia of tuberculosis, employing a number of formulas of different combinations.

Later Morse[2] reported satisfactory results even in severe cases with citrate of iron subcutaneously in the treatment of anemia in infancy. He found the rise in the percentage of hemoglobin was more rapid than that in the number of red blood-corpuscles.

Dickinson,[3] on hypodermic treatment of anemia, says where medicinal preparations fail, when the anemia cannot be relieved, and where digestion is markedly embarrassed by medication, the hypodermic use of iron must be resorted to. Each of these authors speaks of the pain caused at the site of injection.

Of the beneficial effects of arsenic preparations hypodermatically, much has been published in recent years. It is to consider chiefly the use of organic preparations of arsenic in secondary anemia that this paper is written. Our attention was first called to this treatment one and one-half years ago by Dr. Bullock, at Silver City, who showed some results that seemed most favorable and asked one of us (Barlow) to try its effects here.

CASES

Twenty-eight patients were treated, thirteen of whom were in Stage II and fifteen in Stage III.

Many of the first twenty patients had shown little if any improvement on the regular hygienic-dietetic treatment. Some had lost in weight, some had been for a considerable time stationary in weight, and some had gained slowly, though still below their average weight in health. No early case was taken for the reason that such have, without exception, recovered under the routine treatment, or without special agents. It was desired to test the treatment on individuals for whom the routine treatment seemed insufficient. Some of the first twenty cases were looked on as hopeless (2, 8, 14 and 19), and others as capable of nothing more than improvement or arrest (1, 10, 13, 15, 16, 17, 18). In five cases, in Stage II, the prognosis was "fairly good," or "good" (3, 4, 5, 7 and 11); one, in Stage III, was a case of tuberculosis of the larynx, which had healed during tuberculin treatment and absolute rest for the voice for eight months. In this case, the weight had gone down under the higher doses of tuberculin (B.F.), although no febrile reaction was noted at any time, and the low weight was the special indication for the treatment here discussed.

In the second group of eight cases, three were in Stage III, and five were in Stage II, altogether a more favorable class of cases, although one was far advanced (25), and four (21, 24, 25, 28) were capable of nothing more

than arrest or improvement of the disease. In one case, treatment was abandoned after one month because of the complaints of a neurotic patient, and because the injection was followed by such severe reaction at the site of injection, ecchymosis, swelling, tenderness, local fever, etc. This case is not included in the number under discussion.

PREPARATIONS USED FOR INJECTIONS

Early in our experience three patients received Italian preparations, e.g., citrate of iron with strychnin, or metarsenate of iron, etc. As these individuals received the domestic preparations over a much longer period of time, we shall not complicate the report by unnecessary details but shall report on the three principal preparations used: (1) iron cacodylate, (2) sodium cacodylate, and (3) arsacetin.

1. *Cacodylate of Iron.*—This is said to be iron in combination with cacodylic acid, $(CH_3)_2AsOOH$, and therefore an organic form of iron and arsenic. "Those organic arsenic combinations in which the metallic atom is directly attached to the carbon are only feebly poisonous, but in time seem to be changed to arsenious acid in the tissues and may then cause typical poisoning." (Cushny[4]). The combination used is put up in sterile ampules of glass, each holding 1 c.c. of the solution, which is a dose of 0.03 gm., i. e., 30 mg. The solution is of a reddish color, clear and transparent, keeps well without sedimentation or deterioration. When injected beneath the skin or into a muscle, it causes a sharp stabbing pain which passes away, usually within a few minutes, but which has been seen to persist for twelve to eighteen hours. Occasionally, discoloration of the skin, as from ecchymosis, is observed for as long as ten days, either with or without continued pain and tenderness in the part. In one case we discontinued the treatment on account of the intensity of the reaction, the patient being neurotic and reluctant to continue. In nearly all cases there is some induration at the site of injection, although it usually passes away within two days and is not commonly painful.

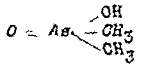
2. *Sodium Cacodylate.*—This contains sodium in combination with cacodylic acid. It is put up in the same sterile ampules as is the iron. It is a clear, colorless, watery solution, and the single dose is 1 c.c., which, in the strength used here, contains 0.05 gm., i. e., 50 mg. This solution also keeps well without clouding or depositing sediment. When injected beneath the skin or into a muscle it causes only slight discomfort or none at all, and we have seen no induration, ecchymosis or continued pain follow its use. When given twice a week, the same site for all injections may be employed if desired.

3. *Arsacetin.*—This is an acetyl derivative of atoxyl and is said to be much less toxic and much more stable than that more familiar drug. Atoxyl is $C_6H_5NHAsO_2$ and contains 37 per cent. of arsenic. Arsacetin is also put up in sterile ampules, each containing 2 c.c. of a 10 per cent. solution which is a dose of 0.2 gm., i. e., 200 mg. When sterilized in dilute solution it does not cloud and keeps better than when in more concentrated form.

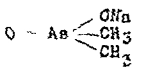
Of each drug a single dose is contained in an ampule and the preparation is sterile and ready for use. A needle 1 to 1¼ inches in length and of small caliber, with a glass syringe of the required capacity (1-2 c.c.), is boiled and after the skin is cleansed with 95 per cent. alcohol, and the solution drawn into the syringe from the broken end of the ampule, the solution is injected deep into some muscle easily reached. We have most commonly used the deltoid muscle. Injections into the gluteal muscle would cause less pain, but the deltoid is very much more readily accessible and the pain is so slight that the patients prefer the more convenient location and offer little or no objection to the discomfort which accompanies it. So far, we have seen no abscess, and with even reasonable care none should occur. Occasionally, we have injected the various drugs just under the skin, but the intramuscular administration seems preferable on account of better absorption. Two injections a week have been given as routine; more frequent administration could doubtless be employed.

(1) Arsenic acid

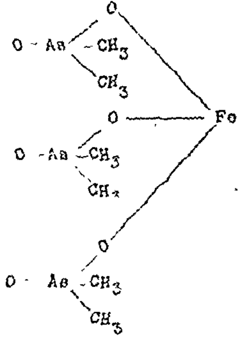
(2) Cacodylic acid (Dimethyl arsenic acid)



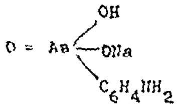
(3) Sodium cacodylate (Dimethyl sodium arsenate)



(4) Iron(ferric) cacodylate (Dimethyl ferric arsenate)



(5) Atoxyl (para-amido-phenyl-sodium arsenate)
(sodium salt of arsanilic acid



(6) Arsacetin (Acetyl derivative of atoxyl)

DEGREE OF ANEMIA BEFORE TREATMENT

In our experience, pulmonary tuberculosis does not cause a severe grade of anemia. The hemoglobin is relatively low as compared with the number of red blood-cells, thus giving a color index of less than 1. In the blood-examinations made before treatment, the lowest estimation of hemoglobin by the Sahli hemometer was 54 per cent., which was accompanied by a red-count of 3,904,000, giving a color-index of 0.69. The highest hemoglobin in this series was 94 per cent., with a red count of 5,472,000, a color index of 0.87. The average hemoglobin content for the twenty-eight cases was 81 per cent., the average red count was 4,904,428, with an average color index of 0.826. Of the twenty-eight counts, sixteen were 5,000,000 or more, while only three were

---

4. Cushny's Text-Book.

below 4,500,000. The rest were between 4,500,000 and 5,000,000.

In the leukocyte counts there was nothing especially noteworthy, for all being advanced cases, clinically, a slight increase in leukocytes was the rule, ten being 10,000 or more, the highest count reaching 15,400. In six cases the leukocytes were under 7,500, in one it was as low as 5,400, this being a case with very little moisture. In general, we may say that the patients with a large amount of moisture, i. e., with copious sputum and many moist râles in the lungs, showed an increase in leukocytes, the increase affecting the neutrophilic polymorphonuclear cells particularly, while the comparatively dry cases showed a normal or low leukocyte count, with the relative proportions normal, or a slight increase in the relative number of mononuclear cells present. This conforms, in a general way, with our ideas based on a much larger number of blood-examinations than we report here. For differential counting of the leukocytes we used the Ehrlich triple stain, fixing the smears by heat and counting always five hundred cells.

EFFECTS OF THE TREATMENT ON THE BLOOD

Of the twenty-eight patients treated, there were two for whom we have no blood-count made after treatment, in one case because the patient had to be sent away as a matter of discipline, and in the other because the patient died suddenly from acute dilatation of the right heart (?). With these exceptions, we can give the record of the blood-examination after treatment.

After treatment, the highest count was 6,170,000, having gone up from 5,216,000. The highest hemoglobin was 96 per cent. (Sahli), which, being accompanied by a count of 5,664,000, gives a color index of 0.85. The average red count in the twenty-one cases which showed improvement in the blood was 5,355,857, as compared with the previous average for the entire twenty-eight of 4,904,428, which is also an average gain, for those twenty who gained, of 542,712. On the other hand, five patients lost in the number of red cells in the blood, all of the five being patients who did badly, except one, who had 5,376,000 at the start, showing an average loss of 319,000 cells per c.mm.

The hemoglobin changes were as follows: twenty-four patients gained in hemoglobin, the average gain being 8.46 per cent., with a maximum gain of 18 per cent. (cases 14 and 25). Two lost in hemoglobin, the average loss being 2.5 per cent., with a maximum loss of 3 per cent. Of the twenty-four who gained in hemoglobin, the average hemoglobin content after treatment was 88.54 per cent. With the average count of 5,355,857, we derive the color index of 0.835, as compared with the average color index of 0.826 before treatment. Thus the type of anemia, in so far as any anemia exists, is unchanged, the increase or improvement affecting the red-cell count and the hemoglobin in practically the same degree. However, we must remember that the number of patients who showed an increase in hemoglobin was twenty-four as against twenty-one who showed an increase in the red count. The improvement in hemoglobin seems, therefore, slightly more frequent in this series than does the increase in the red count.

As to the behavior of the leukocytes under treatment, in general, those counts which had been increased appear to be reduced toward the normal, and the lower counts seem to have been increased slightly. So many other factors affect the number of the leukocytes that we cannot include a full discussion of this feature at this time. Those patients who had shown considerable moisture and profuse expectoration also showed high leukocyte counts at first. As the moisture diminished and the sputum became less abundant, the leukocyte count seemed to diminish. This is not at all unlike the facts as they have appeared in patients not treated by special agents in our experience, and we cannot ascribe any significance to such changes as have appeared within this series, in so far as the leukocytes are concerned. As a matter of fact, of the twenty-six cases, in ten there was a diminution in the number of leukocytes after treatment, while in sixteen there was an increase. The greatest increase was 3,000 and the greatest decrease was 6,400 (Case 5). In differential counting there was nothing of special interest determined, as the relative proportions of the various types of leukocytes seemed still to be dependent on the presence or absence of secondary infection, bronchitis, etc.

We have not separated the cases of those patients who received iron from the cases of patients who had no iron, because there is little difference in the results in the two groups. If any distinction is made, we would say that the patients who had iron show a relatively greater increase in the hemoglobin content of the blood, while those who had no iron show a greater relative increase in the number of red cells present.

WEIGHT OF PATIENTS BEFORE TREATMENT

In all patients treated, the weight before injections were begun was below that given as the average weight in previous good health, which we take as the standard and call "normal weight" for our patients. Three patients had been under treatment by the ordinary means for fourteen months and one had been under observation but one week before injections were begun. The average residence in the sanatorium before beginning the present treatment was 18.4 weeks. One patient was within a half pound of her normal weight and several were within five pounds of normal, but others were far below, one (2) being more than thirty pounds below his normal weight.

EFFECTS OF TREATMENT ON THE WEIGHT

Each patient was weighed once a week, Tuesday morning, and the weight recorded on the special weight chart. Many of the patients had been a long time under observation before they were given special treatment, three as long as fourteen months, two for eleven months and others for shorter periods. In the first group of twenty cases, no patient had been in the sanatorium less than one month, and only three less than two months. In the second group of eight patients placed on the treatment, one man had been under observation but one week when he was given sodium cacodylate. Of all the twenty-eight, nine had lost in weight before the injections, with an average loss of 3.61 pounds, while eighteen had gained with an average of 4.36 pounds, and the weight of one had remained stationary since admission. We have tabulated the weights as they appeared at the end of each month of treatment, for the sake of brevity.

At the end of the first month, seven had lost (average loss, 1.93 pounds), and twenty had gained (average gain, 3.31 pounds). At the end of the second month, twenty-six were still under treatment, although two were not weighed, being too ill for that. Eight had lost (average loss, 1.84 pounds), and fourteen had gained (average gain, 2.50 pounds). This comparison is not with the weight on admission, it is a comparison with the weight at the end of the first month of treatment, showing the change occurring during the second month.

than arrest or improvement of the disease. In one case, treatment was abandoned after one month because of the complaints of a neurotic patient, and because the injection was followed by such severe reaction at the site of injection, ecchymosis, swelling, tenderness, local fever, etc. This case is not included in the number under discussion.

PREPARATIONS USED FOR INJECTIONS

The hemoglobin is relatively low as compared with the number of red blood-cells, thus giving a color index of less than 1. In the blood-examinations made before treatment, the lowest estimation of hemoglobin by the Sahli hemometer was 54 per cent., which was accompanied by a red-count of 3,904,000, giving a color-index of 0.69. The highest hemoglobin in this series was 94 per cent., with a red count of 5,472,000, a color index of 0.87. The average hemoglobin content for the twenty-eight cases was 81 per cent., the average red count was 4,904,428, with an average color index of 0.826. Of the twenty-eight counts, sixteen were 5,000,000 or more, while only three were

CHOICE OF PREPARATION AND DOSAGE

The choice of the drug to be used will depend on the object in view. We would state our preferences thus:

Iron cacodylate is to be preferred:

1. When the hemoglobin content of the blood is relatively low, i. e., when the color-index is very low, say below 0.8. The dose of 0.03 gm. may be given twice or three times a week, changing the site of injection each time. There is apparently more direct stimulating effect derived from the iron solution than from the others.
2. When the patient is not neurotic and will not object to the pain accompanying the administration of the solution.

Sodium cacodylate is to be preferred:

1. When there is any suspicion of syphilis. In such cases we would use 1 c.c. of the 13 per cent. solution (0.13 gm.) three times a week, or at least twice a week.
2. When a painless solution is particularly desired. In such cases we would use 1 c.c. of the 5 per cent. solution (0.05 gm.) twice a week, as being safer than the stronger solution.
3. When there is some degree of secondary anemia, but with a color-index fairly high, as above 0.8.

Arsacetin is to be preferred:

1. When it is to be combined with tuberculin treatment.
2. When sodium cacodylate is not well tolerated.

In all cases we would use 2 c.c. of a 10 per cent. solution (0.2 gm.) and give that amount twice or three times a week, or even daily if it is desired.

CONTRA-INDICATIONS

Although we have seen no harmful effect from the use of these drugs as described, we have avoided administration of them in certain cases:

1. During hemorrhage from the lungs. We have waited at least one week after the sputum has cleared up before resuming injections.
2. During the so-called "asthmatic" attacks of the patients with a great deal of chronic bronchitis and emphysema, fearing to irritate the mucous membranes during such seizures.
3. In all cases in which there was marked albuminuria and cylindruria.
4. Where there has been marked interference with the circulation.

COMPARISON WITH PATIENTS NOT SO TREATED

The question arises: Have we done for these patients more than we could reasonably hope to accomplish for them by the use of the unassisted form of hygienic-dietetic treatment? If we have made the recovery of the later patients (Stages II and III) more probable, more rapid and more comfortable, then the special therapy has been useful. In order to get some light on this question, we have chosen from our records an equal number of similar patients (Stage II, 13, and Stage III, 15), and have studied the condition of their blood and of their weight in the same way as that followed for the others, though reported in briefer form.

The maximum weight gained by one individual, who was not given either iron or arsenic, was 45.75 pounds in a period of twelve months' residence in the sanatorium. The maximum loss of weight in the untreated group was 16 pounds in a period of eighteen months' residence. Both loss and gain, therefore, are in the excess of the loss and gain seen in patients under treatment by injections. Those patients who are treated seem less liable to go far beyond their previous average weight in health, and less liable to lose rapidly and extensively during the course of their illness. More detailed comparison of the separate items will be found in the following tabulated weights:

TABLE 2.—WEIGHT IN TWENTY-EIGHT PATIENTS WHO WERE NOT GIVEN IRON OR ARSENIC

* Average residence 10.95 months.
† Average residence 14.47 months.

THE BLOOD IN TWENTY-EIGHT PATIENTS TREATED WITHOUT IRON OR ARSENIC

For the purpose of this discussion we shall take only the first blood-examination made after admission and the last before discharge. The entire twenty-eight cases are included. The general statements as to the type of anemia are true in all essential particulars when applied to this group, as well as when applied to the group treated. Being the same class of patients, i. e., in the same clinical condition, naturally the blood is about the same. On admission the lowest count (Case 24) was 3,190,000, with a reading of hemoglobin at 60 per cent., which gives a color-index of 0.96, a little higher than usual. The highest count on admission was 5,860,000, in which blood the hemoglobin was estimated at 75 per cent., a color-index of 0.64. The average count of the red cells for these patients on admission was 4,753,000, with an average hemoglobin content of 76.43 per cent., giving an average color-index of 0.81. On discharge the average red count was 4,641,071, with an average hemoglobin content of 79.5 per cent., giving a color-index of

TABLE 3.—TWO GROUPS COMPARED AS TO WEIGHT

	Gained				Lost				No. Not Weighed		No. Dropped		Weighed Same	
	No. Treated	Average (lbs.)	Number Not Treated	Average (lbs.)	No. Treated	Average (lbs.)	Number Not Treated	Average (lbs.)	Treated	Not Treated	Treated	Not Treated	Treated	Not Treated
First month	20	3.31	19	4.18	7	1.93	9	4.0	1	.	.	.	.	.
Second month	14	2.50	22	2.96	8	1.84	5	1.60	2	.	2	.	2	1
Third month	14	2.69	22	2.27	4	1.18	3	0.50	2	.	7	.	1	3
Fourth month	8	2.06	16	2.69	5	1.45	8	1.65	2	1	13	1	.	2
End of residence	17	6.37	18	12.87	9	2.50	10	7.62	2	.	.	.	.	.

During the third month, twenty-one were treated; two were not weighed, four lost with an average loss of 1.18 pounds, and fourteen gained with an average gain of 2.69 pounds. In the fourth month, fifteen patients were treated; two were not weighed, five lost weight (average loss, 1.45 pounds), and eight gained (average gain, 2.06 pounds). A number were continued on treatment for a longer period, some as long as nine months, so that all are collected under one head as "at end of treatment," where a review of weight records for the twenty-six on whom we have such records show that nine lost in weight, with an average loss of 2.50 pounds, while seventeen gained in weight, with an average gain of 6.37 pounds. We emphasize that this is a good record for a class of patients all of whom are moderately or far advanced (Stage II or III—Turban). In all early cases the patients gain in weight without special treatment, a statement to which there is hardly an exception in the experience of this sanatorium.

TABLE 1.—EFFECTS OF TREATMENT ON WEIGHT *

	Number of Patients	Number Who Lost	Average Loss (lbs.)	Number Who Gained	Average Gain (lbs.)	No. Who Did Not Change	Number Not Weighed	Number Dropped
Before treatment	28	9	3.61	18	4.36	1	.	.
First month of treatment.	28	7	1.93	20	3.31	.	1	.
Second month of treatment	26	8	1.84	14	2.50	2	2	2
Third month of treatment.	21	4	1.18	14	2.69	1	2	7
Fourth month of treatment	15	5	1.45	8	2.06	.	2	13
End of treatment........	28	9	2.50	17	6.37	.	2	.

* Maximum gain for one patient under treatment, 25 pounds (Case 20); treated eight months. Maximum loss for one patient under treatment, 5.75 pounds (Case 14); treated eight weeks.

The two patients "not weighed" were both far advanced and were confined to bed for months before death and both became extremely emaciated, although we had no means of getting exact records of weight for either patient. One (Case 2) had not only pulmonary disease but also involvement of the larynx, middle ear and small gut. The other patient was a young girl (Case 8) who had a slowly progressive caseous pneumonia and tuberculosis of the bowel (appendix and colon) who was kept in bed for more than eight months before her death.

The greatest gain in weight occurred in a patient who received the sodium cacodylate treatment (Case 20), while the greatest loss occurred in one who received the iron. The comparison is not a fair one, however, since the last patient had an enteritis of tuberculous origin.

		Iron cacodylate	Sod. cacodylate	Arsacetin

EFFECTS OF TREATMENT ON THE STRENGTH, ETC.

We have no numerical system that will adequately express the results in this matter of strength. Impressions and the personal statement of patients must be cited for what they are worth. Almost without exception, the patients treated say they "feel better" and stronger while under treatment than they did before. Several have asked to be put on injections a second time, simply because they felt stronger while taking these drugs, although the condition of their blood has not demanded a second course. In no case have we noted any effect of poisoning such as is seen in arsenical treatment at times.

We do not believe there has been any direct effect on the temperature of patients from the drug injected, at least none directly attributable to the drug. One patient (Case 10) had continued for several months to show an elevation of temperature to about 99.5 F. each evening, and had suffered from a persistent diarrhea for nearly three months before he began to get sodium cacodylate. After he had received this drug for three weeks, he began to have occasional days when the temperature did not rise as before in the afternoon, and the diarrhea left him and has not returned, though that was nine months ago. In the great majority of our cases no demonstrable change has been observed, although a slight gradual decline in the evening elevation is seen in many cases, such as ordinarily occurs in a favorable individual who has been under sanatorium treatment a few weeks. Certainly, fever is not a contra-indication to this form of therapy.

In so far as the pulse is concerned, we have seen only such changes as are to be attributed to changes in the general condition of the patient. We have seen all of the same changes occur in similar cases who have had no such injections.

The examination of the sputum of our patients has not shown us any ground to believe in the sterilizing action or bactericidal power of either arsenic or iron, or a combination of the two, in the form or dosage here employed. The number of tubercle bacilli in the sputum of our patients showed no alteration other than we could expect from our past experience with untreated cases.

In some cases the patients have claimed to have an increased appetite and improved digestion after beginning the treatment. The fact that such claims have followed the first dose or the first two doses is in favor of an influence largely or purely psychic. We can say, on the other hand, that we have seen no digestive disturbance which we could attribute to the treatment by arsenic or by iron hypodermatically. This is not true of arsenic given in the form of Fowler's solution.

Two patients were suffering from troublesome skin lesions, eczematous in nature. These promptly and thoroughly cleared up after the arsenical preparations had been used but two or three weeks. The result was but incidental to the general treatment.

SPECIAL INDICATIONS FOR ARSENIC OR IRON

In our experience of the past year, we have come to look on certain conditions as being indications for the use of these drugs hypodermatically:

1. When the body weight is below that which has been the average for the patient in previous good health.
2. When the blood shows an anemia, especially when the hemoglobin content is low. We see no reason for believing that the iron is superior to arsenic here, at least none other than the accepted theoretical grounds.
3. When the general strength is subnormal. Here we consider that the drugs act as "alteratives."
4. When, after the usual hygienic-dietetic treatment, improvement is slow or at a standstill.
5. Following a course of tuberculin, when the weight has fallen off, as it so commonly does with the increasing doses.
6. When some psychic stimulus is needed.
7. When there is reason to suspect the presence of syphilis. Here the cacodylate of sodium is to be preferred.

CHOICE OF PREPARATION AND DOSAGE

The choice of the drug to be used will depend on the object in view. We would state our preferences thus:

Iron cacodylate is to be preferred:

1. When the hemoglobin content of the blood is relatively low, i. e., when the color-index is very low, say below 0.8. The dose of 0.03 gm. may be given twice or three times a week, changing the site of injection each time. There is apparently more direct stimulating effect derived from the iron solution than from the others.
2. When the patient is not neurotic and will not object to the pain accompanying the administration of the solution.

Sodium cacodylate is to be preferred:

1. When there is any suspicion of syphilis. In such cases we would use 1 c.c. of the 13 per cent. solution (0.13 gm.) three times a week, or at least twice a week.
2. When a painless solution is particularly desired. In such cases we would use 1 c.c. of the 5 per cent. solution (0.05 gm.) twice a week, as being safer than the stronger solution.
3. When there is some degree of secondary anemia, but with a color-index fairly high, as above 0.8.

Arsacetin is to be preferred:

1. When it is to be combined with tuberculin treatment.
2. When sodium cacodylate is not well tolerated.

In all cases we would use 2 c.c. of a 10 per cent. solution (0.2 gm.) and give that amount twice or three times a week, or even daily if it is desired.

CONTRA-INDICATIONS

Although we have seen no harmful effect from the use of these drugs as described, we have avoided administration of them in certain cases:

1. During hemorrhage from the lungs. We have waited at least one week after the sputum has cleared up before resuming injections.
2. During the so-called "asthmatic" attacks of the patients with a great deal of chronic bronchitis and emphysema, fearing to irritate the mucous membranes during such seizures.
3. In all cases in which there was marked albuminuria and cylindruria.
4. Where there has been marked interference with the circulation.

COMPARISON WITH PATIENTS NOT SO TREATED

The question arises: Have we done for these patients more than we could reasonably hope to accomplish for them by the use of the unassisted form of hygienic-dietetic treatment? If we have made the recovery of the later patients (Stages II and III) more probable, more rapid and more comfortable, then the special therapy has been useful. In order to get some light on this question, we have chosen from our records an equal number of similar patients (Stage II, 13, and Stage III, 15), and have studied the condition of their blood and of their weight in the same way as that followed for the others, though reported in briefer form.

The maximum weight gained by one individual, who was not given either iron or arsenic, was 45.75 pounds in a period of twelve months' residence in the sanatorium. The maximum loss of weight in the untreated group was 16 pounds in a period of eighteen months' residence. Both loss and gain, therefore, are in the excess of the loss and gain seen in patients under treatment by injections. Those patients who are treated seem less liable to go far beyond their previous average weight in health, *and less liable to lose rapidly* and extensively during the course of their illness. More detailed comparison of the separate items will be found in the following tabulated weights:

THE BLOOD IN TWENTY-EIGHT PATIENTS TREATED WITHOUT IRON OR ARSENIC

For the purpose of this discussion we shall take only the first blood-examination made after admission and the last before discharge. The entire twenty-eight cases are included. The general statements as to the type of anemia are true in all essential particulars when applied to this group, as well as when applied to the group treated. Being the same class of patients, i. e., in the same clinical condition, naturally the blood is about the same. On admission the lowest count (Case 24) was 3,190,000, with a reading of hemoglobin at 60 per cent., which gives a color-index of 0.96, a little higher than usual. The highest count on admission was 5,860,000, in which blood the hemoglobin was estimated at 75 per cent., a color-index of 0.64. The average count of the red cells for these patients on admission was 4,753,000, with an average hemoglobin content of 76.43 per cent., giving an average color-index of 0.81. On discharge the average red count was 4,641,071, with an average hemoglobin content of 79.5 per cent., giving a color-index of

TABLE 3.—TWO GROUPS COMPARED AS TO WEIGHT

	Gained				Lost				No. Not Weighed		No. Dropped		Weighed Same	
	No. Treated	Average (lbs.)	Number Not Treated	Average (lbs.)	No. Treated	Average (lbs.)	Number Not Treated	Average (lbs.)	Treated	Not Treated	Treated	Not Treated	Treated	Not Treated
First month	20	3.31	19	4.18	7	1.93	9	4.0	1	.	.	.	.	.
Second month	14	2.50	22	2.96	8	1.84	5	1.60	2	.	2	.	2	1
Third month	14	2.69	22	2.27	4	1.18	3	0.50	2	.	7	.	1	3
Fourth month	8	2.06	16	2.69	5	1.45	8	1.65	2	1	13	1	.	2
End of residence	17	6.37	18	12.87	9	2.50	10	7.62	2	.	.	.	.	.

0.85. Of the twenty-eight cases, fifteen showed an increase in the number of red cells, the average increase for the fifteen being 445,466; thirteen showed a decrease in red cells, the average decrease being 494,615. Comparing the counts on admission with those on discharge, for the twenty-eight we find that in spite of the fact that the number which gained is greater than the number which lost, there is a general average loss of 111,929. This is due to the fact that the individual losses were greater than the individual gains, for the maximum loss was 1,760,000, while the maximum gain was but 970,000 cells.

TABLE 4.—COMPARATIVE VIEW OF HEMOGLOBIN AND RED CELLS

	Average of Red Cells	Average Hemoglobin (per cent.)
On admission—		
Treated	4,904,428	81
Not treated	4,753,000	76.43
On discharge—		
Treated	5,346,000	88.54
Not treated	4,641,071	79.5
Average gain—		
Treated	542,712 (20)	8.46 (24)
Not treated	445,466 (16)	11.66 (12)
Average loss—		
Treated	319,000 (5)	2.5 (2)
Not treated	494,615 (13)	7.14 (7)

TABLE 5.—COMPARATIVE VIEW OF CLINICAL RESULTS

	Treated 28		Untreated 28		Seventh Report 65		Sixth Report 66	
	No	%	No.	%	No.	%	No.	%
Apparently cured	6	21.4	1	3.57	7	10.77	2	3
Disease arrested	10	35.7	5	17.85	5	7.69	8	12.1
Improved	6	21.4	11	39.28	26	40	28	42.4
Progressed	2	7.1	6	21.43	10	15.38	16	24.2
Died	4	14.3	5	17.85	5	7.69	5	7.6
Not treated (ann. rep.)	..	....	..	.....	12	18.46	7	10.3

With the hemoglobin the result is somewhat different. On admission the average hemoglobin was 76.43 per cent., and on discharge, 79.5 per cent., showing an average gain for the twenty-eight of 3.07 per cent. hemoglobin. There were twelve cases showing gains, averaging 11.66 per cent., and seven cases showing a loss of hemoglobin averaging 7.14 per cent., and nine cases in which the hemoglobin content remained unchanged.

In the leukocytes the lowest count was 5,400, and the highest count was 19,900. The counts here correspond exactly with the statements made elsewhere regarding the significance of leukocytosis, and in respect to the type of cells which are actually and relatively increased in number.

On reviewing the results of these control cases, the clinical evidence in favor of the treatment is stronger and more certain than the detailed evidence obtained by the actual weights and blood-examinations. It will be noted that the number of apparent cures has been just as large as that obtained during the seventh year of the sanatorium, although that group contained 17.01 of Stage I, while the group here reported is made up entirely of Stages II and III, the number in whom the disease was arrested was also twice that (in percentage) of those found in the sixty-five cases of the seventh year. This is more than a coincidence, and is more satisfying than the voluminous details, since the future usefulness of the patient and the time of his discharge from the institution, together with almost every other practical consideration, is determined by the clinical condition rather than by any laboratory tests. Dr. Trudeau has well stated this important fact—that careful clinical observation is after all the safest guide we have in the treatment of our tuberculous patients. Dr. Knothe reports from the Hospital of Odessa, April of this year, on cases of tuberculosis treated with atoxyl, saying:

> The value of the arsenic has been ascribed in such treatment to the healing action of the arsenic on the improved blood condition and the nutrition of the organism. To me it appears that the arsenic has, besides this, an actual bactericidal action against the tubercle bacilli within the body. . . . The conclusions from the cases reported may be drawn as follows: Atoxyl exerts a curative action on the disease in question, an activity which, in isolated cases where there is a possibility of comparison, surpasses the activity of the ordinary cacodylate as well as tuberculin, and which not infrequently succeeds without influencing the nutrition of the body, and at times even where weight is lost. I hold to my assertion that the positive results of treatment are to be ascribed to specific bactericidal activity on the tubercle bacilli within the organism.

Our results do not confirm Dr. Knothe's views.

Dr. Peters' paper read at Denver this month concludes that hypodermic injections of iron are practically specific in the secondary anemia of tuberculosis. He considers the iron citrate the best suited in marked anemia, the metarsenate of sodium the best as a general tonic, arsenic and strychnin together to promote metabolism, and finally says that hypodermic injections of iron should always have a place in the treatment of tuberculosis.

CONCLUSIONS

The following conclusions seem to us justifiable, at least in so far as our experience has taught us anything:

1. The subcutaneous or intramuscular injection of sterile solutions of arsenic or iron, or of the two in organic combination, is entirely practicable in the treatment of the tuberculous in sanatoriums.
2. The effects of such medication are seen chiefly in the changes in the blood and in the body weight.
3. The preparations of iron seem to affect the hemoglobin content more profoundly than it does the number of red blood-cells.
4. The preparations of sodium cacodylate and of atoxyl (arsacetin) seem to affect the number of red cells more markedly than the hemoglobin.
5. These solutions are in no sense specifics against the tubercle bacillus, but seem to exert a general tonic or alterative action within the organism.
6. The use of these preparations is entirely safe and is not attended with danger to the patient, even when continued over a period of many months.
7. Relatively larger doses are borne when given thus than are tolerated when given by the mouth.
8. The dosage is capable of exact control and the amount of the drug absorbed is known definitely.
9. The body weight is more rapidly and more certainly raised when these preparations are employed than when the unassisted hygienic-dietetic form of treatment is maintained.
10. There is no demonstrable increased liability to pulmonary hemorrhage accompanying the use of these preparations in pulmonary tuberculosis, even with advanced cases and in the presence of progressive destruction of the lung.

2320 South Figueroa Street.

ABSTRACT OF DISCUSSION

Dr. Samuel D. Swope, Deming, N. Mex.: We find in our part of the country that there is a very marked effect following the hypodermic use of these preparations of iron and arsenic. Many of the people who come to us are in a very low physical state and it is especially noteworthy that we get, as the result of this treatment, a very quick increase in their desire for food, and also in their ability to assimilate the principles thereof. So far as I know in my limited experience no temperature reaction has followed the hypodermic injections of these preparations. There is the suggestion, however, that some of these effects might be due to the hypodermic injections. I find quite a few persons, especially those from the far east, who are very timid, not wishing the injections to be given in the gluteal region; for this reason the injections are often refused. I think that the nervous disturbances may have some effect on the febrile reaction. Dr. Bullock of Silver City, N. Mex., has had quite an extensive experience with this treatment. He reports very satisfactory results and his conclusions are very convincing.

Dr. W. Jarvis Barlow, Los Angeles: Toxic effects from the use of these preparations I have not seen. The reason is, I think, that I have not pushed the arsenic at all and I have kept the patients under treatment for a long period of time. I give these injections of arsenic twice a week; the arsenic is not pushed at all in the class of patients under discussion. I do not see the need of it. I get no rise in the temperature: any rise in the temperature can be attributed to other reasons. Dr. Swope spoke of the patients objecting to the injections being made in the gluteal region. I use the deltoid region and I have yet to find a patient who objected to the injections there. I see no objections to giving the injections in the gluteal region, except that more pain is produced there than in the deltoid region. Dr. Fulton has spoken of the use of these preparations in cases other than pulmonary tuberculosis. I repeatedly see cases that have been carefully watched and which could be compared with tuberculous cases in a similar condition. The results on the blood are not different from what can be obtained by the regular methods. The tonic effects following the injections of arsenic is considerable and are not obtained by me with the employment of other methods.

INTESTINAL APPROXIMATION

A PRELIMINARY REPORT ON A NEW MECHANICAL DEVICE AND A NEW METHOD

JOSEPH B. BACON, M.D.
Surgeon to the St. Francis Hospital
MACOMB, ILL.

About six years ago I announced[1] a new mechanical device for intestinal approximation, called the dumb-bell, from its shape. I have been assured by many of the best American surgeons that the method was a good one, but they stated that the caliber of the dumb-bell used was too small for safety. Accepting this criticism as just, I have made a new instrument which incorporates all of the essential features of the dumb-bell, while I am enabled to increase its caliber by using thinner material. The perfect result of an operation, performed two months ago on a 30-pound pig, convinces me that I am justified in making a preliminary report.

This new device is a simple grooved ring, 3/8 inch wide, 3/4 inch in diameter, made from thin sheet silver, with a forged groove 1/8 inch deep to hold the compressed tissue under a ligature.

The new method of operating and the new device here explained is the result of six years' work. I began with the idea that, in an end-to-end approximation of an intestine, all of the connective tissues must be incorporated in the fixation method in order to safeguard against leakage, and also to get a firm safe union, because it is a well-known fact that the sheath of fibrous submucous tissue is normally both air-tight and water-tight. After experimenting with one device after another, I finally succeeded in making a simple grooved ring (Fig. 1) to accomplish the desired result. It simply acts as a hollow cylinder for the passage of liquids and gas, and at the same time gives a base on which we can tie all the connective tissue in one firm grasp by means of a rubber and silk suture of coarse fiber, and thus have a firm union for three or four days while the serosa and muscularis are becoming united by an organized lymph. In from three to four days the organized tissue is a safe barrier against leakage. The ligature necroses through the connective tissue by this time and frees the device.

The ring is made of thin silver and is very light. There are three different sizes, one for children, one for adults and one for the colon in adults. The same method may be used with a grooved ring moulded from rubber or from any digestible material, but I prefer one of silver, as it can be made small, is light, has a definite strength so that one can do a definite work and know what to expect during a definite time.

We desire the connective tissue to hold at least for three days and prefer it to hold for five days. My experiments on pigs prove that the dumb-bell was freed after from four to six days. The silk ligature should be firmly wrapped around the tissues and the ring twice, then securely tied with several knots; over this should be applied a very light rubber band. The knots and ligatures are left within the canal and the quantity of ligature can make no difference. The ligature material should be coarse, so that it will necrose through slowly, hence heavy braided silk should be used.

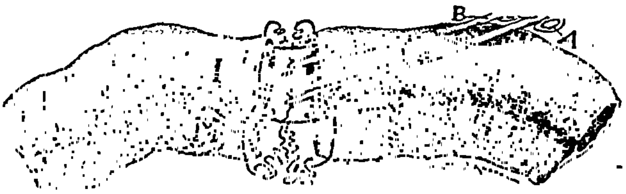

Fig. 2.—Traction sutures grasped by forceps A and B.

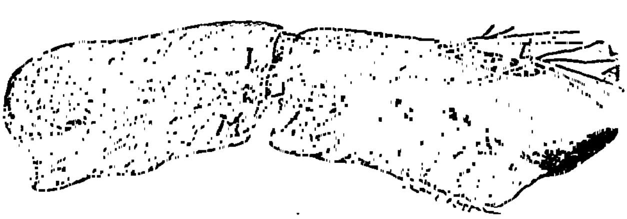

Fig. 3.—The traction sutures in place.

OPERATION FROM END-TO-END APPROXIMATION

The ends of the bowel are secured by a suture at the mesenteric border, care being taken to include in this suture V-shaped mesenteric triangles. Directly opposite the mesentery, on the periphery of the intestine, another suture is placed. Each of these sutures is tied loosely, as they are used only for the purpose of invaginating the two ends of the bowels. Four inches from the proximal end of the intestine, along its peripheral border, an incision is made through the intestinal wall, one inch in length. A pair of forceps is now passed through this incision and into the end of the intestine and the tension sutures secured and drawn through the incision. Now steadying the mesenteric border of the intestine between thumb and finger and drawing the sutures, invaginates the two ends of the intestine into each other and through the incision. The ring is now placed into the ends of the invaginated intestine, being held by special forceps, and the ligature applied at a distance of one-half inch from the ends of severed intestine, encircling it and fitting into the groove of the ring. The operator disinvaginates by gentle traction and pressure on forceps, reunites the peripheral incision with a Cushing suture, then completes the operation by suturing the mesenteric opening. The three sizes of the ring can by the ligature method be made to fulfil any requirement in any operation for intestinal approximation.

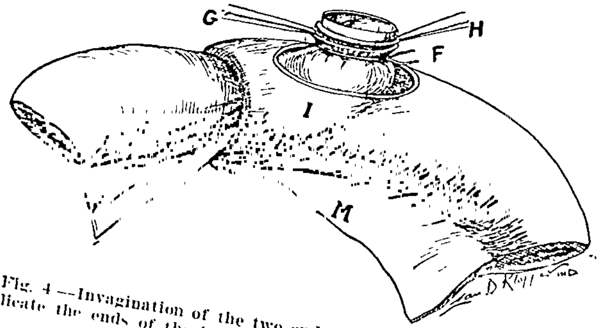

Fig. 4.—Invagination of the two ends of the intestines. G and H indicate the ends of the invaginated intestines; F, rubber ligature.

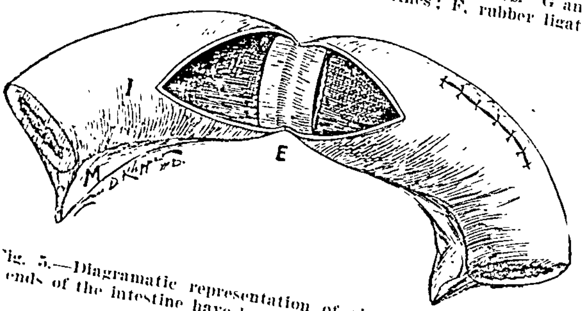

Fig. 5.—Diagramatic representation of ring (E) in place after the ends of the intestine have been disinvaginated.

The advantages of this method of operating are:

1. Simplicity of the construction of the ring; therefore, always ready.
2. Simplicity of the operation.
3. The absolute safeguard against leakage, as the ligature secures all of the connective tissue.
4. The short time in which the operation can be performed.
5. The fact that the ring cannot remain in the site of the operation more than four or six days, as the connective tissue will all have been uniformly necrosed by that time.
6. The fact that the extremely light weight of the ring, its size and shape insure against the possibility of its lodging at any part of the alimentary tract and its large caliber permits the free passage of feces.
7. The fact that no reinforced sutures are necessary.
8. The minimum amount of cicatricial tissue that ultimately remains.

UNIVERSAL GRAVITY OUTFIT

W. T. MEFFORD, M.D.

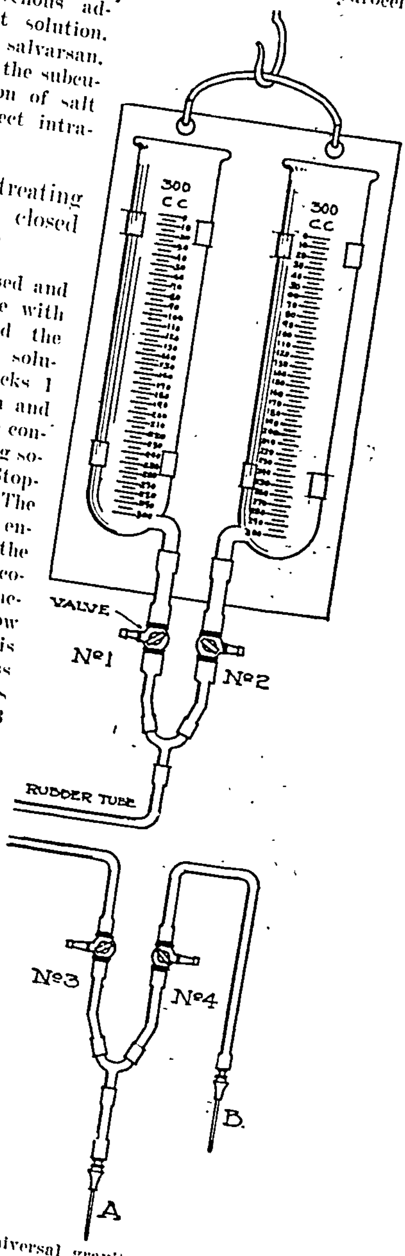
CHICAGO

I have found the outfit here described useful for so many conditions that I wish to bring it to the attention of the profession. It can be used for the following purposes:

The treatment of abscesses by the closed method, as recommended by Sir A. E. Wright; the treatment of hydrocele; irrigation of the bladder; proctoclysis; the intravenous administration of salt solution, defibrinated blood, salvarsan, and other medicines; the subcutaneous administration of salt solution, and for direct intravenous transfusion.

The technic for treating an abscess by the closed method is as follows:

All stop-cocks are closed and the containers filled, one with an irrigating fluid, and the other with the medicated solution to be used. Stop-cocks 1 and 3 are then turned on and the rubber tubing from the container holding the irrigating solution is allowed to fill. Stop-cock 3 is then turned off. The skin where the needle is to enter should now be cleansed, the needle passed through an alcohol flame and the abscess punctured. Turn on the off-flow (Stop-cock 3); Stop-cock 4 is then turned on, the abscess drained, and Stop-cock 4 is again turned off. Stop-cock 3 is now turned on and the cavity filled with the irrigating fluid. When the cavity is sufficiently filled, Stop-cock 3 should be turned off, and Stop-cock 4 turned on, allowing the irrigating fluid to drain away. This procedure may be repeated as frequently as conditions require. After cleansing with the irrigating solution one can, if so desired, turn on any special medicated solution by turning off Stop-cocks 1 and 4, and turning on Stop-cocks 2 and 3, supplying the solution from the container holding such medicine. After filling the cavity with the medicated solution, any part of this solution may be drained away by turning off Stop-cock 3, and turning on Stop-cock 4.



Universal gravity outfit.

The same directions apply to the treatment of hydrocele, and to the irrigation of the bladder, except that the catheter should be used instead of the needle; and for protoclysis, using the rectal tube instead of the needle.

The technic for the intravenous administration of salt solution, defibrinated blood, salvarsan, etc., is as follows:

First sterilize the outfit and all materials to be used, filtering all solutions through sterile filter paper into the containers. Observe the containers carefully and see that there are no small particles floating in the fluid; if so, again filter the solution. Have solutions at a temperature of 100 F. Remove Stop-cock 3 and connect the needle which is to be inserted into the vein directly with the rubber tubing from the containers. Tie a constrictor around the patient's arm to distend the vein at the elbow. If the vein is not sufficiently distended, a few backward and forward motions of the forearm will distend it more. Cleanse the skin over the vein at the elbow with alcohol. Have the needle thoroughly clean, and just before inserting pass it through an alcohol flame. Turn on Stop-cock 1, filling the rubber tubing from the container holding the physiologic salt solution; turn off Stop-cock 1 and insert the needle into the vein. Untie the constrictor, and turn on Stop-cock 1 from the salt solution. When a sufficient amount of salt solution has entered the vein, Stop-cock 1 is again turned off, the needle withdrawn while pressure is made over the vein where the needle enters the skin.

The same technic will apply to the administration of salvarsan and other medicines, except that when the needle is first introduced into the vein the physiologic salt solution should be turned on to see that the needle is in the vein. The needle being properly in the vein, turn off Stop-cock 1, and turn on Stop-cock 2 from the vessel containing the medicine. After the desired amount of the remedy has been introduced, Stop-cock 2 should be turned off and Stop-cock 1 from the salt solution turned on, in order to wash away traces of the remedy that may be left at the point where the vein was punctured. When the vein is sufficiently cleansed by the physiologic salt solution, Stop-cock 1 is turned off and the needle withdrawn as directed above.

For the direct transfusion of blood, the arm of the patient who is to receive the blood, as well as that of the donor, is prepared as directed above for salt transfusion and a constrictor placed above the elbow of each individual. The needles should be thoroughly cleaned by passing them through an alcohol flame just before inserting into the veins. Stop-cocks 1, 3 and 4 are opened, filling the rubber tubing with physiologic salt solution at 38 C. (100 F.). Stop-cocks 3 and 4 are turned off, sterilized needle A inserted into the vein of the individual who is to receive the blood and the rubber constrictor untied. Stop-cock 3 from the salt solution container is turned on to see that the needle is properly in the vein. This having been ascertained, the salt solution is permitted to flow slowly while puncturing the vein of the donor with Needle B. As Needle B enters the vein, Stop-cock 4 is turned on, and Stop-cock 3 is turned off. The constrictor above the elbow of the donor should not be untied until the desired amount of blood has been transfused. After having taken the required amount of blood, the constrictor on the arm of the donor is untied, the needle is withdrawn first from the arm of the recipient in the manner described above, and then the needle is removed from the donor in the same way.

To avoid a hematoma, pressure should be made for a short time over the point where the needle entered the vein. The punctures should be covered with a small collodion dressing.

2139 West Madison Street.

Ancient Surgery.—Surgery is as old as the needs of mankind and its written record extends into the dim past, long before the Alexandrian conquest. It is a disputed theme which one of the two Aryan branches first employed it, but there is evidence that the Hindus possessed a high degree of medical and surgical knowledge, that they performed many plastic operations, among which was rhinoplasty. They also practiced lithotomy quite extensively. Their surgeons removed tumors, did amputations, understood and treated the different varieties of hernias, especially the omental hernia, which was removed by operation on the scrotum. They performed laparotomies, opening the abdomen for intestinal concretions and obstructions. In these cases the incision was made a little toward the left middle line; Cesarean section was also performed, as well as cephalotripsy. Ophthalmology was well advanced and cataract operations were done.—A. M. Crispin in *New York Medical Journal.*

THE INSTITUTIONAL CARE OF YOUNG INFANTS *

THOMAS S. SOUTHWORTH, M.D.
NEW YORK

A recent writer on "The Proper Management of Foundlings and Neglected Infants,"[1] has gone so far as to indicate his belief that the institutional method must give way entirely to the system of placing out in families. He says:

> The first step would be entirely away from institutional care, as the improved feeding-methods and personal hygiene have not had the favorable results expected while the infants are collected and retained in large numbers in one domicile. These old and futile efforts have been long and faithfully tried, and it is time that some other plans be instituted, if the mortality among this class of infants is to be materially reduced.

That the older methods in institutions for foundlings and young infants were productive of a shocking mortality among those under one year of age, has been acknowledged the world over. Nevertheless, reasons existed and still exist for the retention of the institution in some modified form. While some institutions to-day continue to pursue fatalistically the older methods, it must be admitted that others have made marked strides and are presenting very enviable results. But my conviction is that only a beginning has been made, and that far better results can be obtained. The purpose of this paper is, therefore, to call attention to the opportunities and obligations of institutions which receive and care for infants.

FACTORS IN INSTITUTIONAL MORTALITY

The factors which enter into the large mortality in foundling asylums and institutions are as follows:

1. Delay in transmission of the infants to the institution, with resulting disturbance of vital functions and of digestion.
2. Questionable initial care on entering the institution.
3. No wet-nurses, or too few wet-nurses, for premature and delicate babies.
4. Bottle-feeding from birth, or sudden weaning on reception in the institution.
5. Inadequate facilities (milk laboratories or diet kitchens) for preparing bottle-feedings.
6. Routine artificial feeding, with but slight individualization.
7. Insufficient nursing force, which precludes the normal personal attention to each infant.
8. Large wards with ready extension of infectious and contagious principles.
9. Overcrowding, with lack of air-space and of proper ventilation.
10. Insufficient provision for outdoor airings.
11. Inadequate facilities for the application of quarantine, in its broadest sense, to all sources of infection in infancy.

It may be remarked that I have given no prominent place to the requirement of clean milk and of methods intended both to keep it sweet and to limit bacterial growth. This is necessarily included in the proper preparation of artificial feedings, and its importance has been unduly exaggerated and attention thereby diverted from other measures of equal if not greater urgency.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

[1] Chapin, Henry Dwight: Med. Rec., New York, Feb. 18, 1911.

Such degree of success as has been attained by the institutions which now show the more enviable records has come to them in proportion to their recognition of the adverse factors which I have enumerated.

To put this reorganization of institutions for infants on a logical basis, we must not be content with the correction of isolated errors; we must go far enough back to discover the fundamental reasons for their abnormal mortalities. In this search, we may start from the premise that as a rule the lowest mortality obtains where infants receive not only the mother's breast-milk, but also her personal care in the home. It matters little how primitive the home, if there be competent breast-milk and individual care, the prospects of survival for an infant, healthy at birth, are excellent. Remove one of these factors, and the risk is greatly increased. We have daily cause to recognize this added risk when artificial feeding must be resorted to, even in a home where there is maternal care. Deprive the infant both of breast-feeding and of home care, and at once the outlook becomes an exceedingly serious one.

While institutional environment undoubtedly contributes its own special dangers, it is generally recognized that when breast-fed or bottle-fed infants in an institution are accompanied by their mothers, they do relatively better than infants correspondingly fed who have no maternal attention. Such success as the placing-out system has obtained is dependent in very considerable part on restoring to the infant individualized care in the substitute home. Therefore, since breast-milk and motherly care in the home are the foremost factors in preventing early mortality, and experience has shown us that possibly either one of the two, but *never both*, can be dispensed with without incurring the greatest risk, it follows that just in proportion to the ability of the modern institution to furnish these to infants will be its success in preventing their deaths and rearing them as normal well-nourished children.

Nevertheless, it is just these two factors which are most lacking in the majority of institutions, and until they are supplied more adequately, it cannot be claimed that the limits of success in the institutional care of infants have been reached.

We may now return to the consideration of the special factors which call for readjustment.

Transfer to the Institution.—The institutional life of an infant is usually preceded by some period of stress in the home from which it comes. This may be due to the illegitimate birth of the infant, the death of the mother, her serious illness, or merely to the mental anxiety associated with increasing poverty or the breaking up of the home. These instances will suffice to indicate that the infant, whether breast-fed or bottle-fed, has usually suffered more than ordinary deprivation and neglect. Then follows the transportation of the infant, often unsuitably clothed, to the institution. Possibly the first application is made with the infant at the police station, the office of some charitable organization or some general hospital. This may involve long waits or another journey. If the baby is taken in at some temporary receiving station, misguided sympathy gives the infant some unsuitable milk mixture to still its cries. Eventually it reaches the institution, suffering from unwonted exposure to heat or cold, fatigued, and probably with a disturbed digestion. In short, infants on reaching the institution are so rarely in normal condition that I recall one institution in which it was the routine practice to enter the condition of all such infants as "hopeless," in order to avoid criticism in the event of their later demise. The partial solution of this problem should lie in better arrangements at all charitable centers and receiving stations for prompt attention to such infants, and for immediate transfer to their proper destination.

Reception and Attention at the Institution.—When the child is received into the ward, the probable previous experiences should be borne in mind. If it has been exposed to cold, it should be given a warm bath to restore the circulation, enveloped in warm clothing and placed in a warm bed. Every institution receiving such infants should be equipped with suitable appliances for maintaining the temperature of feeble and exhausted infants when this is below normal. Premature infants are especially vulnerable. The incubator has gone out of fashion. It easily got out of order, and fresh air was rarely supplied in sufficient quantity. Its place has been taken by enveloping suits of cotton-wool and cheese-cloth, and by padded baskets in which the body heat is maintained by hot-water bottles, or—much better—by electric heating pads. A "warm room," in which abundant fresh air is heated uniformly to 80 F. or thereabouts, will in time come to be a necessity in every well-appointed institution for infants.

Nourishment.—The nourishment of the infant following its reception is a matter of great importance. Bearing in mind its previous experiences, this is a moment for caution. If the child has been previously breast-fed, this is a particularly inauspicious time for beginning total artificial feeding. If the infant has been fed artificially, in an ignorant or haphazard fashion, the digestion is probably more than ordinarily disturbed. Rest and fluid in the form of boiled water are more advisable than food, unless this be very simple—barley water or whey. Exact information as to the infant's previous food is rarely obtainable. A mild laxative to clear the digestive tract of the injudicious offerings of solicitous friends or strangers is a wise preliminary to the beginning of a cautious line of feeding.

Temporary Wet-Nursing.—For many of these infants, temporary wet-nursing should be provided. No other measure offers an equal chance of restoring digestive balance. While the sudden weaning which takes place on the transfer of an infant to the hospital is so often the beginning of a more or less prolonged period of malnutrition ending in death, wet-nursing for a few days will permit the gradual introduction of bottle feeding, and is not only more rational, but more frequently attended with success. Whatever may be said of the ethics of wet-nursing in private practice whereby the life of the wet-nurse's child is often sacrificed in order to save that of the foster-child, wet-nursing in the institution has neither this drawback nor is it impracticable. It is simply a question of dollars and cents.

Breast-milk is purchasable. Institutions which undertake to confine and shelter prospective mothers without pay should, very properly exact an agreement that the women will nurse another baby besides their own, as a partial return for what they themselves receive. Homeless mothers can be found who are glad to accept the shelter of the hospital while earning something for the future, through the sale of part of their breast-milk. Circumstances should determine the manner of payment. Exceptionally willing nurses may be paid a lump sum per month. For others, the transaction should be on the strictly commercial basis of so much per ounce for the breast-milk furnished. This plan, followed at the Sänglingsheim at Dresden and elsewhere, at once assures the cooperation of the wet-nurse. She is more ready to confine herself to a proper milk-making diet, since the larger flow of milk is to her advantage. The quantity taken from the breast is easily determined by weighing the baby before and after nursing. It is stipulated at the start that she is to nurse any baby assigned to her. To ensure this being done, milk, when drawn from the breast and fed from the bottle, is paid for at a somewhat lower rate.

By furnishing temporary wet-nursing, it is possible for the institution to compensate its infant inmates at crucial junctures for the serious loss of maternal nursing.

Artificial Feeding.—Even with a reasonable provision for wet-nursing, the majority of infants in any institution must be fed artificially. This is far from being a simple matter. It is generally admitted by all who have had any experience in this direction that it is much easier to feed artificially a group of infants who are cared for in their homes, even though the homes be poor ones, than to feed successfully a similar group in an institution ward. Furthermore, if institution infants are fed on condensed milk, simple dilutions of cow's milk with sugar and water, or even with a few inelastic percentage formulas of what is commonly called "modified milk," a considerable proportion of the results will be unsatisfactory, and the deaths, especially among very young infants, numerous. Every institution should possess a supply of clean cow's milk, and a milk laboratory or kitchen thoroughly equipped and sufficiently elastic to permit of individualization of the infants in their feeding, and the employment, as required, of every modern scientific aid. Only with such aids, backed by experience in their application, can the mortality of artificially fed infants in institution or hospital wards be reduced to a reasonable minimum. Such a milk laboratory and its maintenance cost money, but it is well expended for the results are to be measured in human lives.

Even with these facilities conscientiously applied, however, there are certain infants who, from failure to absorb their carefully adjusted food, or frequently also as the result of intercurrent disease, lose steadily in weight. Under such circumstances, in private practice the resort is to a wet-nurse with a reasonable prospect of staying the decline and reestablishing normal digestion and absorption. The institution or hospital infant has a right to similar treatment before it is deemed hopeless and condemned to die on a regimen which has already proved inefficacious. Wet-nurses employed by the institution have here another important field of usefulness. It is not necessary that such wet-nursing should be continued indefinitely. When, with gain in weight and restored digestive functions, the infant has been lifted out of the danger zone, artificial feeding may be resumed. This is at first partial, enabling the wet-nurse to give more of her milk to other needy infants, and in time it is made total. A few nursings a day often enable an infant to assimilate more successfully the bottle-feedings which furnish the most of its nourishment.

We have now pointed out the lines along which the institution may progress in compensating infants for the loss of maternal nursing, and may turn to the ways in which the loss of individual care and protection in the home may be more properly compensated.

Large Wards.—Unquestionably, the building of the large wards which prevail almost universally in hospitals and institutions had its origin in the desire to care for the largest possible number of patients, with the aid of the smallest possible number of nurses or attendants. While the evils of this policy can, where adults are concerned, be largely overcome by increase of the nursing staff, the noxious influences of the large ward on children are too numerous and too insidious to be met solely by such measures. The late Mark Twain said that in the home "one baby was a riot, twins an insurrection, and triplets a full-blown revolution." The average mother or nurse in the home would be considered in danger of overwork in giving proper care to three infants. Many institution wards, however, are constructed to house from sixteen to twenty-four infants, while during the day three attendants, of varying degrees of experience, and one at night, would be considered a liberal provision, even when the ward contained a number of sick infants. Such disproportion, even if it allows for the more necessary services, certainly precludes any of the refinements of motherly solicitude, which, in some indefinable way, aid in keeping a baby in good condition.

Overcrowding.—Aside from the lessened attention given each infant, the overcrowding of wards has unquestionably a deleterious effect on young infants. Because infants are small and their cribs small, they are often allowed less air-space than the adult. Just the reverse of this should obtain. Oxidation is much greater during the normal rapid growth of infancy. Free ventilation is therefore imperative. This calls for properly screened windows open at all seasons both day and night. Fresh and not overheated air, now demanded in the treatment of disease, has no less place in the welfare of infants (not premature) who are nominally well. Even with careful attention to ventilation, it is a common experience to find that when a certain number in each ward is overstepped, all the bottle-fed infants begin to do less well.

Probably the greatest menace to the infant in the large ward is infection. The element of added risk, when the infant leaves the comparative seclusion of its own home and enters the populous ward, is scarcely computable. Suffice it to say that the chance of infection is multiplied by the number of other inmates in the ward, since, with a few exceptions, the infections to which it is liable come most commonly from other children, and not from adults.

In speaking of infections and contagions, it is natural that we think first of those popularly associated with infancy and childhood. Scarlet fever and mumps play less part among the very young. Diphtheria is somewhat better controlled than formerly, through antitoxin immunization, but repeatedly breaks out in unexpected places through the agency, probably, of unrecognized bacillus carriers. The exclusion of specific vaginitis calls for constant vigilance. Whooping-cough and measles spread easily, defy ordinary formal quarantine, and cause, both directly and indirectly, many deaths. Illnesses which are regarded lightly in the home assume a more serious import when they occur in a ward of bottle-fed infants who are with difficulty maintaining their weights or even making moderately satisfactory gains. Chicken-pox stops gains and claims some victims among the feeble. Thrush ("sprue") is a serious and often fatal disease in such a group, costing marasmic infants a pound or more of weight, a loss which many cannot survive.

This by no means completes the list of dangerous infections. I am inclined to the belief that two other groups of infections actually cost more lives in institutions having large wards. I refer to the communicable infections of the gastro-intestinal tract which predominate in the summer months, and the communicable diseases of the respiratory tract, which occur chiefly, but not exclusively, in the winter months. Whatever improvement there may have been in other directions, little attention has thus far been paid to isolation, quarantine and other preventive measures for these conditions. There is growing evidence that ward epidemics of intestinal disturbance of varying degrees of severity travel from patient to patient, or arise from common causes not traceable to the milk. Ward epidemics of nasopharyngeal disease are easily recognizable, carrying in their train otitis media, pneumonia and cervical abscess. Isolation in its broader application is not only not practiced, but cases of pneumonia, frankly infectious, are rarely removed from the general wards in which they appear, unless it be for treatment by cold air or in special medical wards. It may be claimed that it is practically impossible to isolate all cases of potential infection in our institutions. If, however, it be really impossible to take measures for the limitation of avoidable illness, the main fault lies with the construction and arrangement of the building. If infections of all kinds are to be limited at the outset, the large ward with many inmates must go.

The construction of new institutions and hospitals for infants must therefore include, primarily, smaller wards, preferably containing four, but not more than six beds. Each ward should have its own toilet and bathing-room, and a smaller room opening out of it, in which any patient showing doubtful symptoms may be placed by the nurse. Each ward should also have a section of veranda on which the infants may be placed in lined and padded baskets on all favorable days. The influence of such outdoor airings on the health, color, digestion and growth of infants has been demonstrated. Each ward should have its own semipermanent nurse or nurses. A more intimate relation will thus be established between the nurse and her charges, a more definite responsibility felt for their welfare, and an honorable pride and rivalry in their progress will be stimulated. With such arrangements, the composite element of "hospitalism" should be largely eliminated. If infants and young children of different ages are assigned to each small ward, conditions will more nearly approximate the home and more personal attention will be secured for the infants. Where training-schools for nurserymaids exist, the training acquired will fit them more suitably than at present to meet their responsibilities when they enter private service.

I am no opponent of the placing-out system, but until we recognize the fundamental defects of the older types of institutions, and cutting loose from tradition and error, rectify them, calling nothing impossible or impracticable until it has been tested under favorable conditions, we certainly are not justified in saying that the institutional care of infants is a failure. The future institution, built and organized to avoid present-day mistakes, should, in view of the showing made by the best of the old-type institutions, attain a proportionately greater measure of success. Then, as now, the most favorable results will be secured, not by the abandonment of either, but from organized cooperation of both systems.

807 Madison Avenue.

ABSTRACT OF DISCUSSION

Dr. Gustavus Eliot, New Haven, Conn.: The most wonderful cures I have known of in children ill with digestive and diarrheal troubles in summer have followed the carrying of children from the city to the country. This leads me to emphasize the point that such institutions for the care of children should be removed from the city and erected in the country. The buildings should not be the elegant three- or four-story buildings such as are often seen in the cities, but they should be low buildings so constructed that after a few years' use they may be destroyed and clean new buildings take their place. The location of such an institution in the country also gives an opportunity for improvement in the treatment of these children in regard to their food. They are fed to a great extent on cows' milk, and if in the country, they can receive milk that is absolutely fresh and clean. In the feeding of these children, fresh milk twice a day should be used instead of the milk that is now used, which is twenty-four to forty-eight hours old when it reaches the consumer. These two things, country air and fresh, clean milk, are most important factors in the treatment of infants deprived of a mother's care.

Dr. J. W. Cokenower, Des Moines, Iowa: In twenty years work in the Iowa Children's Home, in the admission of babies much trouble has been caused us because we could not get a complete history. We have found that in nearly all such institutions nine times out of ten the infectious and contagious diseases have arisen from receiving diseased patients. This we have partially overcome. One must look after the excretions and secretions and deal with them in any way that wil bring the best results. After that is done, no routine method will fill the bill. Individual cases require individual feeding We use barley water, and sometimes have employed prepared foods and malted milk, but it is the exception and not the rule when we have been able to use them advantageously But cows' milk has been our chief dependence and we try to keep that absolutely clean, and have much better results Often we have children brought to us in such a condition that we are unable to do good work. The stomach absolutely refuses to retain anything, either food or medicine, and there is such a generally relaxed condition that we cannot give i by the rectum; then as a last resort we have used quinin and olive oil, making an inunction and wrapping them in cotton and oiled silk. In that way we feed and medicate them until we have given the digestive organs a rest and can feed them otherwise, and in this way have saved several children that I believe we would otherwise have lost.

Dr. Langley Porter, San Francisco: I think no one could have presented a more forcible argument against institutions than Dr. Southworth in the paper he has just read. I believe that twenty years from to-day no one in this Section of the American Medical Association will make a plea for the retention of the institution. In San Francisco we have persuaded the Children's Agency of the Associated Charities to do away with their foundling asylum and to board out the children with the result that the death-rate has been reduced from 40 to less than 2 per cent. But the care of the babies in the institutions is really a very small part of the question. The real problem is to educate the public in caring for children When a baby is boarded out, the result is that the older children in the family are being trained to the proper care of children, and that is the first and greatest advantage in the boarding-out system. A second advantage is the decrease in the death-rate that always follows. The boarding-out system is of economic value, also, for the reason that in the fixed charges of such an institution, as Dr. Southworth has described, we tie up a large amount of money and also pay out much money to people for the care of these children. If you were to divide this money among the many needy families allowing them to care for these children, you would get better value for the money than if it were tied up in capital. believe that before many years have passed Dr. Southworth will be as ready to condemn institutions as any of us.

Dr. I. A. Abt, Chicago: I agree for the most part with the last speaker, though I think it will be many years before we can abolish infant hospitals and asylums. Some place mus be provided where we can send babies that are destitute and require immediate care. I think the infants' asylum or hospital is valuable just in proportion to what is put into it. It is of value just in proportion to the amount of soul and brains put into it. If you want results you must have a technic that provides for asepsis and cleanliness, good food and good care. This must be carried out with determination, and in the end you will save a goodly proportion of your children. In boarding-out cases, the result depends very largely on the character of the women who receive the patients. I have seen both ways tried. In the boarding-out system very often it is a mercenary matter with the women who take the babies. So far as wet-nurses are concerned, it has been said that an infants' hospital has no more right to exist without the wet-nurse than the adults' hospital without an operating room. I think that is true. If you desire to reduce the infant mortality, wet-nurses are absolutely necessary, especially in the summer when the mortality is high. In our own hospital in Chicago we have as many wet-nurses as we need. We found we could train these women to produce large quantities of milk. They milk the breasts and produce several quarts per day. As to the prevention of infection I think very often our technic needs to be perfected. It seems to me we are not careful enough about our hands, and sometimes the nurses infect a child. It all comes to this, that we must educate the educators, particularly physicians and nurses. Mothers and nurses should be taught how easy it is to carry infection from one child to another; not only vulvovaginitis, but a host of other diseases. Each baby ought to have its own individual property, its own toilet articles, its own powder box, even its own thermometer. Another important thing is the feeding of children when they first come to the hospital. I think we have gone too far in the matter of starvation of babies. I think that when a baby is brought in pinched, blue and cold and is given barley water for a prolonged period his weight-curve goes down and if he does not actually starve, at least he falls a ready victim to infection. I believe that starvation is an important element not only in causing the immediate death of the infant but indirectly predisposes to death from infection. Another matter of importance is the question of cathartics. I am convinced that many of these babies are physicked sick. If they have had a cathartic on admission and the intestinal tract is clean, what is the sense in giving them continued carthartics? I think the matter of starvation and the matter of over-catharsis should be emphasized, because at present they are often applied in a routine way without due reference to the condition of the patient.

Dr. T. C. McCleave, Berkeley, Cal.: Dr. Porter omitted to mention a very important feature of the work in San Francisco. This work was undertaken about two years ago. The mortality under the old system was about 40 per cent. and during the first year under the boarding-out system it dropped to 20 per cent. Then, an organization in the city making it possible for these children to be given certified milk, the mortality dropped in the second year to what it now is, about 2 per cent. Dr. Southworth spoke of clean milk. I think the meaning of that word "clean" is not always clear. In the feeding of infants and also of adults sick with various diseases, we know the wonderful change that results from putting the individual on certified milk. Therefore I want to urge on you particularly that you turn more and more to the use of certified milk. We have in California a strong organization of milk commissions, and we have a constantly increasing demand for certified milk. We are engaged in a vigorous propaganda among the laity for certified milk, as well as among the profession, but it is unfortunately true that it is often easier to get a response from the layman than from the physician.

Dr. Jessie McGavin, Portland, Ore.: I do think that one of the most important things is to see that the nurse carries out the physician's orders. It means a constant looking after the nurses until they are thoroughly trained, and when the nurse once understands that you are a crank, and that your orders must be carried out, you will save more of your babies. I lost one baby by neglect on the part of the nurse in the matter of feeding. In regard to contagious cases, in one instance I found a contagious hospital and a general hospital adjoining and the place simply swarming with flies. We need to educate the hospitals in these conditions. As to pure milk, in Portland we have had one epidemic with a very high mortality as a result of dirty milk. All physicians were losing cases. We have had a fight for pure milk and as a result our mortality is lessened.

Dr. T. S. Southworth, New York: Perhaps in some sections of the country the boarding-out system can be employed exclusively, but as I see conditions in the East it will be impossible for a long time to come. The sectarian organizations will be loth to give up their institutions. We still have a considerable field for improvement in our institutions and what I have said applies also largely to babies' hospitals. I recently saw a statement to the effect that being a baby should be classed as an extra hazardous occupation, and it is very true. I did not refer to the glass partitions, for such partitions are valuable just so far as you can depend on your nurses. The glass partition is merely a danger sign board. Speaking of food, we have certainly need of milk which is clean. However, we must not only have suitable milk, but it must be used in the right way. There has been too much talk in this country about the saving of life by pasteurization alone. As to the limitation of infections, reference has been made to the danger of the patient's bringing in infectious diseases on admission. I admit this is a serious matter, but a great deal of infection is introduced into the institution by the visits of parents or relatives. The outbreaks of the ordinary infectious diseases in the wards are directly proportionate to the number of friends allowed to come to see the children. Often a parent will come directly from the bed-side of a child sick with scarlet fever or other infectious disease.

INFLUENCE OF SUMMER HEAT ON DIARRHEAL DISEASES *

I. A. ABT, M.D.
CHICAGO

A first glance at infant-mortality tables demonstrates the fact that the greatest death-rate occurs from the gastro-intestinal diseases during summer. Dr. W. D. Booker, in the presidential address before the American Pediatric Society in 1901, reviewed the early literature on this subject. Dr. Booker says that the records show that in about the middle of the eighteenth century there occurred along the Atlantic coast of North America a serious disease characterized especially by vomiting and diarrhea and was confined almost exclusively to children in the first two years of life. Its incidence was limited almost to the summer months and it appeared each year in an epidemic form, with such regularity that it was looked for as an annual visitor. In 1777, Benjamin Rush read a paper entitled "An Inquiry Into the Cause and Care of Cholera Infantum." He gave a description of the stools, etiology and treatment of the disease. He denied the etiologic importance of dentition, worms and summer fruits, and he thought that the disease was similar to cholera and remitting fever in adults. He did not attempt to explain any relation of the disease to atmospheric heat, but contented himself by saying that the disease seldom occurred in Philadelphia until the middle of June and generally continued until the middle of September, and that its intensity and duration were always proportionate to the heat of the weather. The first indication for treatment, he thought, was to evacuate the stomach by emetics, followed by an abundance of water or tea, or an infusion of blueberries. He also suggested enemas, plasters to the abdomen, and internally he recommended port wine or white wine. The best results were obtained when a little water was mixed with the wine. He considered baths very important and he said his principal dependence had been placed for many years on country air. As prophylactic treatment he recommended, (1) a daily cold bath, (2) clothing which was appropriate to the conditions of the weather, (3) removal of the children from the city to the country. Rush says: "I have never known but one instance of a child being affected with this disease, who has been carried into the country in order to avoid it."

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixty-Second Annual Session, held at Los Angeles, June, 1911.

It was thought at this time that the disease was peculiar to America as, apparently, the condition had not been described in other countries. It was thought to be due to the character of our climate, to the severity, frequency and suddenness of the change of temperature and to the sudden transition from winter to summer without the intervention of a gradually opening spring.

The mode of action of atmospheric heat in causing cholera infantum was the subject of controversy and various theories were advanced in explanation of it. These were for the most part based on the prevailing conception of the existence of a cutaneo-hepatic sympathy. By some, the heat of summer was supposed to exhaust the tone of the skin or to disturb its healthy action and thus determine an undue quantity of blood into the abdominal viscera, causing a congestion of these organs. Booker goes on to say that others thought that the effect of protracted heat led to a disturbance of the digestive organs because of some deranged condition of the exterior surface of the body. In this way the tone and energy of the stomach became impaired and consequently the system became more accessible to impressions exercised by external agents and its resistance to them became diminished.

So far as the geographical distribution of the disease is concerned, it is noted that in the extreme north or south, the sick-rate and the death-rate are low. In North America, the middle and western states contribute the largest numbers in the mortality figures. As one approaches Canada, the numbers diminish; in the South and Southwest, we are told, the disease is less common. It is rare in the tropics, as has been observed in Brazil and in the tropical and subtropical regions of Asia and Africa. The same points in vital statistics apply to European countries. The summer diarrheal diseases occur most frequently in the large centers of population, particularly the industrial centers and in those regions where artificial feeding is commonly employed, and where the climatic conditions are such that the summers are relatively hot and the winters cold and severe.

The older American physicians, particularly Rush, thought that the hot weather was the most important factor in the etiology. He advised taking the child from the city to the country. In the course of time, other writers thought that the hot weather alone was an insufficient cause. Some said that the summer diarrhea of infants was a species of Asiatic cholera; others, that it was a form of malaria. In America, some writers considered it akin to yellow fever and others thought it was due to an indefinite miasm. Virchow thought that the condition stood in some relation to the water-supply and drainage, or to the surface water, adopting the view Pettenkofer applied to typhoid fever. In short, the older views as to the etiology of summer cholera considered that the disease was due to exogenous agents, the action of which was favored by the external heat, the latter acting either directly or through the food.

When the bacteriologic era began the attempt was made to find specific microorganisms. Escherich differentiated an exogenous infection of the intestines, the so-called streptococcus enteritis, and an endogenous infection, a process which ran its course as an auto-infection, or an infection of the chyme. Escherich thought that the disease might be produced by infected cow's milk, microorganisms gaining access to the milk shortly after milking, or that endogenous decomposition occurred as the result of already sick or enfeebled children receiving such milk. In the intestinal canal, irritating organic acids were believed to be produced, or alkaloidal products, ptomains, which produced diarrhea and nervous symptoms. No specific microorganism was found, but various forms, he thought, were capable of producing such a reaction. Other authors described epidemics of summer diarrhea, particularly in hospitals and asylums, and naturally thought that the epidemics were bacterial in origin. Baginsky, who failed to find a specific microorganism, came to the conclusion that the saprophytic bacteria in the milk were capable of producing poisonous peptones from the proteids. He thought that indol, phenol and ammonia gained access to the lymph and blood and produced toxemia. It is a well-known fact that bacteria multiply rapidly in milk during hot weather and it was thought that this was the sole cause. This led to sterilization and pasteurization of milk. Flugge and all the other authors who have described the poisonous effects of milk in producing summer cholera have compared this condition to meat-poisoning. But this comparison does not hold in all details. Meat-poisoning and sausage-poisoning affect all persons, whether they be children or adults, who have partaken of this food. It might be said that children are more susceptible than adults, though as a rule not all children who partake of supposedly infected milk fall ill. On the other hand, Vaughn has described epidemics of poisoning by ice-cream and cheese, affecting every person who partook of the food. They fell severely ill with vomiting, diarrhea, pain, weak, irregular pulse and great pallor or cyanosis. He isolated a poisonous substance which he called tyrotoxicon. No further argument need be advanced that the summer complaint is not similar to tyrotoxicon poisoning.

Czerny and Kellar believe that summer diarrheas are for the most part the result of exogenous fat-decomposition due to the presence of bacteria; they think that this condition is related to the heat of the summer only in so far as the increased number of microorganisms are rendered more active. But there are numerous objections to this theory. If it is true that bacterially acidified milk is toxic, why is buttermilk devoid of toxicity and why so acceptable, even to the sick infant?

In brief, it may be said:

1. The bacterial toxicity of milk is not proved.
2. On the other hand, a bacteria-laden milk is more likely to produce diarrhea than milk poor in bacteria.
3. In those cases in which a toxic product has been isolated from milk or meat, nearly all persons who took such food were rendered severely ill. An analogy of this condition with summer diarrhea is not tenable.
4. It is very probable that bacteria play a part in summer diarrhea, but they do not act on the milk before it is taken into the body (exogenous), but more likely cause fermentation after the food has been received in the gastro-intestinal tract (endogenous).

The bacterial explanation for the summer diarrhea is not sufficient. Why the excessively high mortality only during the hot weather? How may we explain the fact that the hotter the summer, the greater is the sick-rate and the death-rate among infants?

If during a hot day one examines the conditions under which the infants live in homes of the poor, one will be impressed by the fact that the temperature indoors exceeds the temperature outdoors; that at night, if the temperature outdoors has fallen considerably, the temperature indoors is considerably higher. The babies are frequently put to bed overclothed and sometimes excessively covered with bedding. If the infant's temperature be taken even before diarrhea has set in, he is frequently found to have 100 to 101 F. Many writers have looked on this condition as one of insolation or heat-stroke.

The interesting fact has been brought out that seven times as many artificially fed children, as breast-fed, die in summer. The bottle-baby is at greater peril in summer than at any other period of the year. No matter what theory may be advanced, the fact that breast-fed children show greater resistance and immunity than bottle-fed children cannot be denied. Those infants who have previously suffered from gastro-intestinal derangement, or even those who are convalescing from some alimentary disorder, are likely to show a hyperthermia on the advent of hot weather. This is undoubtedly due to the fact that the heat-regulating mechanism is much more unstable in children suffering from digestive disorders, and we may say that such children are predisposed to heat-stroke.

It is not possible to say in what manner the heat affects the body of the child, but it seems that the infant's resistance is lowered and that injuries by food are readily produced. It is not known whether the heat produces changes in the enzymes of the digestive tube. or whether the bacteria make toxic products or irritating acids in the gastro-intestinal tract. It is possible that the epithelium of the gastro-intestinal tract is itself damaged. It would be unscientific to say that bacterially decomposed milk has no causal part in producing summer diarrhea; but on the other hand, proof is insufficient to permit us to say that bacteria play the single rôle. It would seem that the increased heat, particularly of the home, is an important etiologic factor. Whether this be due directly to heat-stroke or whether it be, in the sense of Finkelstein, a diminished tolerance for food and the possibility of injury by food, must remain for the present an open question.

Perhaps this latter point will explain the difference in death-rate between breast-fed and hand-fed infants. The tolerance for breast-milk is always greater than the tolerance for cow's milk, and similarly, immunity and resistance is greater in breast-fed than hand-fed children. A word should be said against the practice of keeping sick infants warmly dressed and excessively covered during the hot weather. A cool bath and the out-of-doors temperature are important indications in treatment.

The occurrence of high sick-rate and death-rate during the summer cannot be explained by a single cause. We believe that the condition is due to a combination of causes. Infected milk has a deleterious influence, but it must be considered along with the direct influence of heat, especially the excessive warmth of the home. It would be unwise to deprecate the advantage of sanitary milk, but the problems of hygienic housing, the avoidance of overclothing, the importance of taking the child out of doors and of frequent bathing are important points which cannot be overestimated in consideration of the summer diarrheal diseases of infants.

Finkelstein, after discussing the bacterial theory of summer diarrhea, thinks that infection occurs in those cases in which the gastro-intestinal cells have been previously damaged. He is willing to admit that delicate children who ingest bacteria-laden milk are liable to have gastro-intestinal infection or that damage may be produced by preformed acids and peptones in the milk. The two arguments in favor of infected or decomposed milk as cause of gastro-intestinal disorders were: the increased morbidity and mortality during the summer, and the fact that the greatest proportion of those that sickened and died were bottle-fed infants, while breast-fed children were for the most part immune. But Finkelstein thinks this insufficient. He thinks that the majority of infants who sicken or die during summer time are injured by the heat. The cases begin acutely, show symptoms of hyperpyrexia and the trouble may be cured or even prevented by reduction of the patient's temperature or by providing cool, sanitary living conditions. The heat lowers the individual tolerance of the infant and predisposes him to gastro-intestinal disorders which are likely to assume great severity.

If it is asked why breast-fed children enjoy immunity against the injuries produced by excessive heat, it may be answered that the child suffering from digestive disturbances has less resistance to heat than a normal child, since most breast-fed children are well, and a goodly number of hand-fed children are more or less ill, the conclusion is obvious.

ABSTRACT OF DISCUSSION

Dr. John W. Foss, Phoenix, Ariz.: In Phoenix we have probably the highest dry-bulb temperature and the lowest wet-bulb temperature during the summer, of any place in the world. We have no acute dysentery in children in the summer. We consider the summer the healthiest season for children. In fact, we have very little sickness of any kind among children at that time. So I think this question of heat is practically eliminated as the cause of this class of diseases in children, judging from the experience we have had in our climate. There are few places which have less physical discomfort from heat during the summer than Phoenix. As an illustration of this fact, 15 per cent. of humidity with the thermometer at 106 F. at Phoenix is as comfortable as 70 is at Chicago ordinarily, or the dry-bulb thermometer would have to register 133 at Phoenix to cause as much discomfort as 90 per cent. of humidity with the thermometer registering 98 F. at Chicago. It is probably this remarkable climatic condition which is so conducive to the health of children. Our experience would seem to prove that the mere question of heat has nothing to do with these diseases, especially at Phoenix. The wet-bulb rarely goes above 72 F. in Phoenix in the summer time, while the dry-bulb will sometimes run as high as 110. Evaporation and radiation are very rapid here on account of the pure dry air, moderate wind velocity and varying atmospheric pressure.

Dr. M. A. Weems, Columbia, Tex.: I think this question can be explained by the humidity. In Arizona at the time the air is so dry the evaporation from the body of the child is so rapid that it keeps the body temperature low even in extremely hot weather.

Dr. W. V. C. Francis, Los Angeles: I think one factor in the etiology of summer diarrheas is very obvious, in that the condition occurs in large cities. In Los Angeles we have none of the really poor and none of the overcrowding that you have who live in large cities. I believe a large factor in the diarrheas of children is the lack of fresh air. If you remove the slum districts and the overcrowding, you will do away with a lot of the summer diarrheas and deaths.

Dr. Frank P. Gengenbach, Denver: Undoubtedly there are many factors to be considered in the cause of summer diarrheas in children, but I am inclined to believe with Dr. Abt that heat does have something to do with it. Recently we had an early and sudden hot spell for Denver, and in my own private practice I saw distinct disturbances among the babies. This is an instance in which the ideas of Dr. Francis do not apply, for these babies were in well-to-do families, well provided for, well cared for, and had plenty of fresh air. I think that some depressive factor in connection with this hot spell certainly did disturb the babies. Probably in hot weather the babies cannot stand as rich a food, as high in fat, and it disagrees with them. Often it is not necessary to take them off the food, but if I take off the cream and give skim-milk mixtures they rapidly improve.

DR. FRANCES M. ALLEN, San Diego, Cal.: In my experience of six years in Illinois in a children's institution, the children were cared for by mothers who boarded the children for $2.50 or $3.00 a week each, and our results showed that we could keep our mortality low, except during the hot spells. During five years we had a high mortality only during August, during the sixth year, in July.

DR. L. T. ROYSTER, Norfolk, Va.: To me this is one of the most interesting and difficult phases of the diarrhea question. I come from the Atlantic coast, where the humidity is high, and where a temperature of 88 F. is very uncomfortable, while a temperature of 100 F. out here I have not found at all uncomfortable. In April the temperature rises considerably; then during the first two weeks of May we have a considerably cooler spell, and then the temperature shoots up and the minute the temperature goes up the trouble begins. I can almost predict the number of my calls by the reports of the weather bureau. In June we have a high death-rate. In July and August we have a decreased mortality, so I believe the humidity must have something to do with it. Another interesting fact is this: I have practically no consultations in summer diarrheas from the country. Yet there the temperature is just as great and the humidity is just as great; but I practically never see a child from two miles out with a summer diarrhea. Again, I practically never see a case among breast-fed infants. If a sick child is brought to me in the morning and it is taken for a boat ride for the day, it will come back in the evening 95 per cent. better. In fact, we have tried to train the mothers to take the children to the sanitarium when they first become sick, without waiting to see a physician, even, and it is really surprising how rapidly they improve, even though the institution is located but 50 yards from the shore. Another thing is the character of the discharges. These vary from year to year. One year there will be a watery discharge with the same prostration and again the next year we may have a remarkable number of dysenteric discharges, so that from year to year the discharges are markedly different.

DR. I. A. ABT, Chicago: I think the fact has been brought out by investigators, even as far back as the time of Benjamin Rush, that summer diarrheas are more prevalent in the temperate regions, while further south and even in the tropics, the disease is scarcely known. In my own part of the country there is a striking relationship, I am sure, between the condition of the weather and the summer diarrhea. I think anybody who has lived east of the Mississippi River will not doubt that. Why New Orleans should have a low death-rate with an increase of temperature I confess that at this moment I am unable to see. I am not sure that the heat is the only factor, but it does seem that all over the world where cases are being studied and where men are trying to solve this problem, during July and August there is the highest death-rate. It is true the condition is more common in the cities than in the country, but the condition is not confined to the cities by any means. I brought up this question because it seems to me we ought to study the cause of these summer diarrheas. The war that is being waged all over the world to save babies needs some help from the educator. We urge that every effort be made to save babies and I think it is very important that we attempt to arrive at some definite conclusion as to the cause of trouble. I would suggest that a committee be appointed from the various communities and that this committee be asked to keep a record of their observations and that they submit a report based on such records.

TWIN PREGNANCY IN UTERUS BICORNIS

PHELPS G. HURFORD, M.D.
ST. LOUIS

In view of the rarity of pregnancy in the uterus bicornis, with viable fetus, I think the following case of sufficient interest to report. The patient was referred to me by Dr. George M. Tuttle.

History.—Mrs. E. B. C., a cultivated American woman, aged 34, was seen by me in March, 1911. She was then about four months pregnant and very uncomfortable, having pain much of the time from what appeared to be uterine contractions, also much pain due to attacks of acute indigestion. The bladder was very irritable and for about three months she had had to get up three or four times at night to urinate.

The patient had one child living, a girl 5 years old, in perfect health; this child was born prematurely at eight months and had thriven from birth. One other baby had been born prematurely at about seven and a half months and had lived seventeen months, dying of some intestinal infection. With each former pregnancy, Mrs. C. had had similar pain and discomfort, and all efforts to prevent premature labor failed.

Examination.—The patient was apparently in good general condition but somewhat nervous over the prospect in store for her. She was about four months pregnant. The fetal movements could not be felt; the heart-beat could not be heard. There was unquestionably a notch in the upper middle portion of the uterus, but no importance was attached to this finding. A mass could be made out on either side. It was now learned that, whereas in previous pregnancies there had been movements and contraction pains only on the right side, they were now present on both. The urine was examined repeatedly and was at all times normal.

With careful dietary and some medication the patient went along more or less uncomfortably (mostly more) for two months. She was up for a time every day but went out very little. Later examinations convinced me that there was something radically out of the way in this case. Movements and heart-beat could be readily made out on the right side but never on the left; the separate masses could be easily distinguished. June 3, the threatened miscarriage became imminent; sedatives had no effect. True labor pains began and on my second visit dilatation was well advanced. After the patient had progressed favorably through the night, the pains unaccountably stopped early in the morning. Dilatation was then complete and the membranes were ruptured. It was now found that the umbilical cord was through the pelvic inlet and the head beside and above it was not engaged. The cord was pulsating and the child and the mother were in good condition; as yet it could not be certainly demonstrated that twins were present. Dr. Tuttle saw the patient at this time and thought twins a strong probability. Although it was probable that interference would be necessary it was decided to wait a while longer.

Delivery.—That evening artificial delivery was performed under chloroform anesthesia. Dr. H. J. Storrs was called in consultation and agreed to the necessity. He suggested the possibility of a twin pregnancy in a bicornuate uterus. Version was performed and one living and one dead child delivered. A septum divided the uterus to a point well below the umbilicus and a fetus occupied each side; both were vertex presentations. The placenta of the dead child showed the site of the hemorrhage that had provoked the miscarriage. The uterus contracted promptly and then showed two separate fundi, each larger than the fist, and separated by a notch so deep that the clenched fist easily rested in it—a typical uterus bicornis. There was no appreciable difference in the size of the two horns.

Recovery.—Convalescence was uneventful, the patient sitting up on the eighth day. Involution proceeded normally, and after two months a vaginal examination showed clearly the two cornua, each about the size of the normal fundus and separated from each other enough to allow the two examining fingers between them. The notch extended nearly to the supravaginal portion of the cervix.

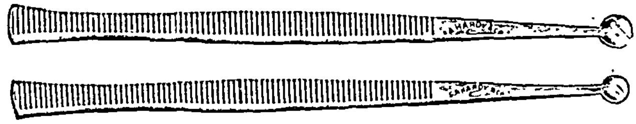
CIRCULAR BLADE, HOLLOW AND GUARDED CHISELS

ADVANTAGES OF THEIR USE IN MAKING BONE-FLAPS

D. MILTON GREENE, M.D.
DETROIT

When performing operations on the skull and antrums, I have for years been impressed with the fact that when a bone-flap is to be formed and replaced, with the expectation of its preservation and ultimate reuniting, as in the "Beck frontal antrum operation," it is highly important that its periosteum be not detached, because the bone, as is well known, derives its nutrition largely from it. This is especially true in operations in presence of pus or infection, for the bone-flap must under such circumstances have more and better nourishment, and more perfect coaptation than would be necessary under aseptic conditions, in order to preserve its vitality, and insure its integrity and ultimate reunion.

Should the periosteum become detached from the bone-flap in performing the Beck operation, necrosis would follow, necessitating removal of the bone, which would cause scarring and depression deformity, and would be a great calamity to both the patient and the surgeon; this is true of any operation for the formation of a bone-flap, where its preservation is essential. Detachment of the periosteum is usually caused by splintering the bone in cutting it with chisels. The splinters and fractures which occur in bone-flaps, made by chisels, are always due to the wedge shape of the chisels used. When a wedge-shaped chisel is driven into bone, the "chip" or part so cut has to rise or be displaced to make room for the bit or blade of the chisel, and is thereby split or fractured at the junction of the incision and the uncut bone, just in proportion to the thickness of the chisel at that point. Every time the chisel is driven into the bone, it splits or fractures it in the manner above stated, so that when the bone-flap is completed, there will be a series of splits or fractures around its edge, with consequent separation of a portion of its periosteum, with a liability of complete separation of the bone-flap from its periosteal covering.

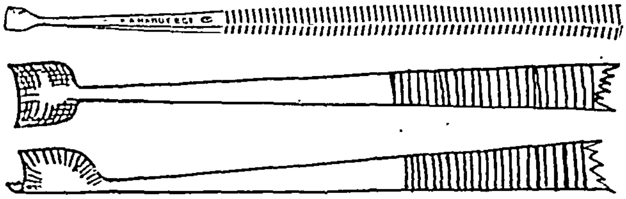


Figs. 1 and 2.—Two circular blade chisels.

I have devised a set of chisels which overcome in a large degree the difficulties mentioned, and which are useful in many operations on the skull and antrums, especially in forming bone-flaps and in operations within the nose. They are so constructed that they may be driven into the bone without producing any fracture. These chisels are new in design and original in the philosophy of their use and effect. There are five chisels in the set: two circular blade chisels (Figs. 1 and 2) one hollow chisel not unlike a "square shovel" (Figs. 3, 4 and 5), one guarded chisel with straight bit, and one guarded chisel curved on the flat.

They may be described as follows: They are six inches in length, with formed, milled handles; two are made with circular blades, beveled on both sides or surfaces, so that they will cut in every direction, except where the handles join the blades; one is made with a blade 7 mm. and the other 8 mm. in diameter, and about 1 mm. thick at the junction of the handles with the blades. They are so constructed that when driven into bone, the only place the incised bone has to yield is at the center of the blade, and there only 1 mm., while at the circumference (at the edges of the incision), where the incision joins the uncut bone there is no displacement, and, therefore, no splintering or fracture takes place.

The third chisel of the set is called a "hollow square blade chisel," and is not unlike a square shovel in form (Figs. 3, 4 and 5). The blade has a curve of about one-fourth of a circle, is sharp in every direction, and has the same cutting effect the circle blades have. This chisel is used in cutting a circular flap in any operation, and may be used in removing turbinates, septal shelves, spurs, and in opening into the antrum of Highmore.



Figs. 3, 4 and 5.—Hollow chisel not unlike a square shovel, beveled from center to all edges, leaving the thickest part at handle and in the center. Side view and front view.

The other chisels of the set are called guarded chisels: they are made with handles the same as the others, ending with flat blades, 7 mm. wide, 1 mm. thick and 3 cm. long. The cutting edge is beveled from both sides in the center, making edge 4 mm. wide, and concave, with a guard at each corner, which is 1 mm. square, 2 mm. long and rounded (blunt) at the end. These act as guides as well as guards. One has a straight blade (Fig. 6), while the other is curved on the flat (Fig. 7); the latter is designed especially to be inserted beneath the bone-flap in the Beck frontal antrum operation, to cut the partition or bony septum of the antrum. The guards guide the chisel, and cause it to follow the bony septum, no matter how crooked it may run. These chisels may also be used in removing turbinates and septal shelves, and for various operations where guards or guides are needed.

There is one precaution necessary in using these chisels: The force necessary to drive them through bone is much less than that required in using ordinary chisels, because the resistance is reduced to a minimum, therefore, great care should be used that they are not driven beyond the point desired.

Fig. 6.—Straight guarded chisel.

Fig. 7.—Curved guarded chisel.

712 Jefferson Avenue.

Economic Importance of Health.—If the citizen is diseased, his usefulness is curtailed; if as a result of disease he is maimed, crippled or blinded, he often becomes a burden to the community; if his life is thereby cut short, his services are ended. Has anyone ever calculated the economic loss to the country that might be materially reduced by giving the same attention to the preservation of the human species as is given to animals?—White in *Journal of the South Carolina Medical Association.*

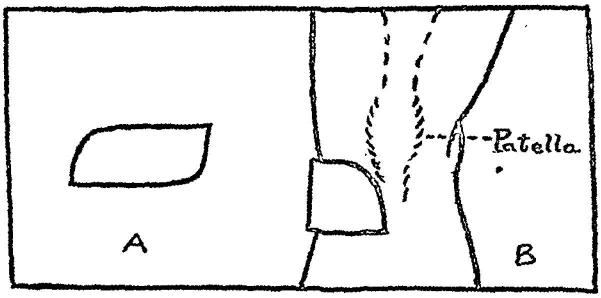
TREATMENT FOR SLIP-MENISCUS

GEORGE CHANDLER, M.D.
KINGSTON, N. Y.

Slip-meniscus, or dislocation of the internal semilunar cartilage of the knee-joint, I have found to be of very frequent occurrence, and more often in females than in males. Standing on one foot solidly, as when on a step-ladder or chair, and making a quick move or inward rotation is the most common cause of loosening the cartilage. The internal condyle of the femur pressing against the cartilage, by this quick motion, displaces it inward, moving it on the upper surface of the tibia and thereby rupturing the coronary ligaments. It rarely comes from a fall or from slipping. The quick rotation would not displace the cartilage if the foot were not placed solidly on the ground and the weight of the body all on that leg. The symptoms are pain in the joint, quite severe, made more so by the complete extension of the leg, comparative ease when the leg is in semiflexed position and marked tenderness on pressure over the cartilage itself. There is usually very little swelling, though it may occur.

The following treatment I have been using for the past ten years with very marked success, and I have described it to other physicians, who tell me that their results are also very satisfactory.

For these cases I always have in my office several pieces of sole leather, cut, approximately, to the shape shown in the illustration at A, about 4 inches long by 1¾ inches wide. I fit this leather to the inner aspect of the knee-joint as indicated at B. By first putting the leather in water, soaking it thoroughly and whittling the edges so that it is smooth, it may be *molded* into shape. I then strap this piece in position over the cartilage by adhesive straps, two up and down, one horizontally and one oblique, making four in all; then a firm, though not too tight, bandage of the coat-of-mail type is applied over the knee. If the bandage is voluminous, it need not be put on tightly, as it will give splendid support without shutting off the blood-supply.



Treatment of slip-meniscus; A, sole leather cut for application; B, leather applied to the knee.

I allow the patients to walk the same as usual, though they complain of some pain or rather soreness, which wears away in three or four days. I have them report in ten days when I reapply the same leather under a fresh bandage. After about three such treatments, the patients are well and only a bandage needs to be applied. I think the irritation of the leather which supports the cartilage in its natural position causes an aseptic adhesive inflammation to take place between the cartilage and bone; this takes the place of the ruptured coronary ligaments.

The advantages of this treatment are, its simplicity, its efficacy and the fact that patients can continue at their occupations while undergoing it. In fact, it removes all the attendant inconveniences of this painful condition and places it, to my mind, in the same category with a sprained ankle, when the latter is treated by the modern method of adhesive straps and walking.

11 East Chestnut Street.

SUCCESSFUL USE OF THE STAPHYLOCOCCUS SPRAY ON DIPHTHERIA CARRIERS

S. R. CATLIN, M.D., L. O. SCOTT, M.D.,
AND D. W. DAY, S.M., M.D.
ROCKFORD, ILL.

Early in January, 1911, an epidemic of diphtheria broke out in Rockford Hospital. With the appearance of the first case, all ordinary precautions of isolation, giving of antitoxin, etc., were employed.

The appearance of a second case made it evident that infection might be general throughout the institution, and we were appointed a committee in charge with power to institute any measures necessary to prevent an epidemic. Antitoxin was administered to all known contacts, and daily routine cultures from the throats of all inmates were made and examined. A quarantine for clinical cases was established in a separate building, and an isolation ward for carriers in another.

While no patients at any time developed the disease, within about two weeks from the appearance of our first case, a total of twelve clinical cases had developed among the nurses. Of these twelve, eight had received, from four to ten days previously, immunizing doses of from 1,000 to 2,000 units of Illinois State Board of Health antitoxin.

Five hundred cultures were taken during the epidemic from a total of seventy individuals. As a result of these routine cultures, twenty-two persons were found to have the diphtheria organisms in their throats without manifesting clinical evidence of the disease. In other words, out of a population of seventy people, 17 per cent. developed diphtheria, and 31 per cent. became carriers. As stated above, these carriers were isolated in a separate building. Release from isolation or quarantine was only granted after at least three negative cultures.

During the early stage of the epidemic, the ordinary methods of throat antisepsis were used, such as spraying with liquor antisepticus and 50 per cent. alcohol. In spite of all methods, certain individuals remained carriers for days. Two clinical cases that had been released from quarantine after three consecutive negative cultures were again found to harbor the diphtheria bacillus. Two persons were released and reisolated three and four times, respectively. Our most persistent carriers, however, were nurses who at no time gave clinical symptoms. In some instances it was found that nose cultures were positive when throat cultures were negative.

At about the height of the epidemic, Prof. Norman MacLeod Harris, of the University of Chicago, was invited to go over the situation with the committee. He verified without exception all culture findings that had been made. He recommended the use of a spray of broth culture of *Staphylococcus pyogenes aureus* as a means of ridding the throats of the diphtheria organism: a method first introduced by the Danish physician, Schiotz,[1] and later successfully tested by Page[2] of Manila.

There was opportunity to test this method in eight cases, all carriers. A twenty-four-hour old bouillon culture was sprayed into the nose and throat two or three times daily, all other treatment being stopped. In no instance did any harmful condition develop as a result of the introduction of the staphylococci.[3]

Two nurses, previously persistent carriers for days in spite of all antiseptic measures, failed to give one positive diphtheria culture after the first application of the staphylococcus spray. Three nurses, each having had one positive culture previous to the use of the spray, were constantly negative thereafter. One nurse had one positive culture after using the spray, and one other had three positive cultures after employment of the spray, and then became negative. The eighth nurse was persistently positive in spite of, as supposed, the daily use of the spray; but it was later discovered that she had evaded using it as directed; more careful control of her use of the spray immediately cleared her throat of all diphtheria organisms.

CONCLUSIONS

1. The ordinary immunizing dose of diphtheria antitoxin does not always protect an exposed individual against the disease.
2. Only by regular and constant taking of cultures can institutional epidemics of diphtheria be controlled.
3. The usual methods of throat antisepsis are of little value in ridding the throat of diphtheria bacilli.
4. Treatment of the nose is as important as treatment of the throat.
5. In institutional epidemics, more than one series of three negative cultures is necessary for release.
6. Results with *Staphylococcus aureus* spray were such as to warrant recommending its further use.
7. Apparently no harm results from the application of the spray.

THE TRANSFUSION OF BLOOD

FURTHER NOTES ON A NEW METHOD *

ARTHUR H. CURTIS, M.D., and V. C. DAVID, M.D.
CHICAGO

In a previous paper[4] was presented a detailed preliminary report on a new method for the transfusion of blood. At that time we expressed the opinion that the accepted methods of transfusion then in vogue were not adapted to general use and were not highly satisfactory even in the hands of those skilled in surgical technic and experienced in blood-vessel surgery. Evidence that others shared this opinion is afforded by a survey of recent literature, which contains numerous descriptions of ingenious devices contrived for the purpose of making this important operation one which can be performed by any competent surgeon. Especially deserving of mention, in addition to the well-known cannula of Crile, are the devices of Brewer and Leggett,[5] of Janeway[6] and of Sorese,[7] all of whom have given valuable reports of their studies in this field.

A more extended experience with our method of transfusion has resulted in the introduction of certain modifications in the technic, without radical alteration of the original procedure as previously described. The apparatus (see illustration) consists of a large glass bulb with two cannula tips, and a rubber tube with a glass syringe attached. The glass bulb is sterilized by the dry method and the inner surface coated with paraffin. The paraffin coat is best applied by pouring hot paraffin into the open end and then rotating the bulb to secure a uniform coat. The two cannula tips are then heated and each in turn dipped into melted paraffin and shaken to make a thorough coating so as to keep the excess from occluding the lumen. The syringe and rubber tube are prepared by boiling.

With the apparatus now ready for use a one-half-inch incision is made over the most prominent vein of the elbow region in both donor and recipient. The donor's vein is then clamped at the distal end of the incision, stripped, ligated proximally, cut below the ligature and washed out with 1 per cent. solution of sodium citrate. The recipient's vein is ligated distally, stripped toward the heart, clamped at the upper end of the incision, cut above the ligature and also washed out. The cannula tips are moistened by introducing a few drops of liquid petrolatum through the bulb end, then inserted into the respective veins of donor and recipient and are ligated in position. Aided by the use of a shoulder-constrictor blood rapidly enters the bulb when the donor's vein is released. As the blood rises in the tube a covering cap of liquid petrolatum is added to relieve surface tension. The rubber tube is now fitted over the top of the glass bulb, and the tube and syringe are used to produce positive and negative pressure as desired. (The bulb usually fills without resorting to suction.) The donor's vein is then held by the fingers, the recipient's vein released and the blood introduced into the latter at any desired rate of flow. When the bulb is nearly empty the recipient's vein is held and that of the donor released, thus allowing the bulb to again become filled with blood, after which the process continues as before. Bulbs of various sizes ranging in capacity from 100 c.c. to 400 c.c. have been used. Experience indicates that the largest size are, as a rule, the most satisfactory.

In experiments extending over a period of nearly a year transfusion has been performed according to this technic, on an average, from one to two times weekly. A considerable number of the animals have been killed and autopsy performed at the close of the experiment. Others have been examined after being kept for periods varying from one day to five weeks. From a study of the animals under observation following transfusion, we are convinced that the blood received by them functionates in a normal physiologic manner. In no instance have the clinical manifestations or autopsy findings revealed evidences of ill effects.

We have performed four transfusions in human patients according to this modified new method. In these operations were found two obstacles not encountered in experimental work. The first difficulty met was lack of blood in the donating vein, as a result of which only 300 c.c. were obtained. Since the time of this operation (Transfusion 1) we have used a constrictor around the arm of the donor and no longer want for blood. The second difficulty arose in one instance and was due to the unusually small size of the basilic vein of the recipient, who was a delicate woman with cubital veins little larger than those ordinarily found at the wrist. After transfusing this patient with

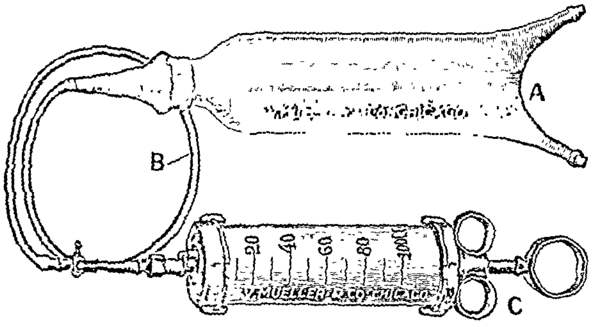
250 c.c. of blood it was decided to change transfusion tubes because of delay incident to readjusting the arms of the donor and the recipient. The remaining portion of the recipient's vein was unfortunately found to be too small to admit the cannula and in preference to operating on the other arm further work was postponed. Previous experience in performing transfusions with the Crile cannula leads us to think that veins of annoyingly small caliber as were found in this patient would be rarely encountered. As a safeguard, however, bulbs with small-sized cannula tips should be held in reserve.

Clinical improvement, as manifested by the general condition as well as by increase in the percentage of hemoglobin and in the number of red blood-corpuscles, was obtained in all patients. In the two least satisfactory cases, discussed above, in which were given respectively 300 c.c. and 250 c.c. of blood, the patients showed as much improvement as those successfully transfused by the usual artery-to-vein anastomosis. In fact, despite general opinion, 250 c.c. of blood probably equals the amount ordinarily obtained by most methods.

The other two transfusions were performed without difficulty or complication. Blood in abundance was available in both instances. The most striking result was obtained in a patient in Presbyterian Hospital, under the care of Dr. James B. Herrick and Dr. N. Sproat Heaney. The clinical findings were those of a sepsis of unknown origin complicated by uterine hemorrhages. For several days preceding transfusion the temperature, which was 103.2 F. at the time of operation, ranged from 102.5 to 105 F. Respirations before transfusion were from 40 to 44 per minute; the pulse, 140 per minute, thready, and of small volume. Blood examination showed 4,400 leukocytes, 2,800,000 red blood-cells and 45 per cent. hemoglobin. The patient was aroused with difficulty from a semicomatose condition; 1,050 c.c. of blood were transfused. Improvement in the general, physical and mental condition of the patient was immediate and remarkable. The respirations fell at once to 24 per minute. After four hours the pulse was 134, in eight hours 120, in sixteen hours 112, and in twenty-four hours 108 per minute. The temperature at the end of four hours was 100 F., in twenty-four hours, 100.6 F. During the week following, it ranged from 99 to 101 F. Examination of the blood after twenty-four hours showed 3,750,000 red blood-cells, with hemoglobin 55 per cent. "at least" (Dare). For three days the blood findings remained essentially the same, then gradually improved until the patient was discharged at the end of eight weeks with a red count of 4,600,000 and hemoglobin of 75 per cent. The leukocyte count varied from 4,400 to 6,100. Repeated daily examinations of blood-smears were negative. There were no nucleated red cells, no evidence of unusual variation in their size and no phagocytosis or other evidence of their disintegration or destruction.



Device for transfusion of blood. A, glass bulb with cannula tips; B, rubber tube fitted over bulb and connected with C; C, syringe used for exerting positive and negative pressure as desired.

Thanks are due Drs. Graham, Herrick, Irons and Heaney for clinical material furnished and interest manifested in this work.

31 North State Street.

A SIMPLE METHOD FOR THE MECHANICAL TREATMENT OF GLENARD'S DISEASE

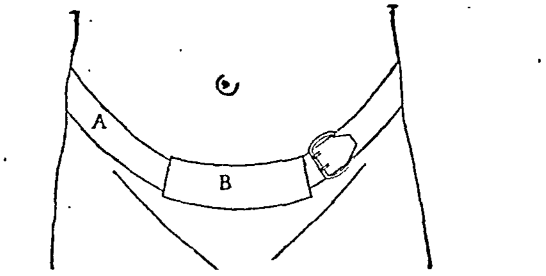
G. W. McCASKEY, A.M., M.D.
Professor of Medicine, Indiana University
FORT WAYNE, IND.

The treatment of splanchnoptosis is one of the most difficult problems confronting the practitioner, and especially is this true of the rather extreme type of cases which fall into the hands of the internist. We need all the help we can get from every possible angle, mechanical, medicinal, etc. The pathology is many-sided and its successful therapeutics must be equally so. While attending to other features of treatment, in many cases mechanical support of some sort is absolutely essential.

For many years I have been trying a great variety of mechanical supports as adjuvants in the treatment of this condition, including corsets, bandages of various sorts, with various modifications of the adhesive plaster support suggested by Dr. Rose. These adhesive strips, variously modified, have given me better results than anything else. Considerable difficulty, however, has been encountered on account of the extensive application of the plaster to the skin, the tendency being to roll up, produce cutaneous irritation and thus interfere with its continuous use. The mere application, without wrinkling, causes dermatitis in many cases. In order to accomplish permanent results, it must be kept up for a long period of time. Recently, in order to escape some of these difficulties and at the same time retain the advantages of adhesive plaster, a combination of the latter with the bandage has been used. The primary object is to get the point of support as low on the abdomen as possible. The support should be easily removed, its tension readily adjusted at any time and the area of plaster applied to the skin reduced to the minimum, in order to limit the extent of the skin irritation, when, as often happens, this results from the contact of the plaster.

A strip of zinc oxid adhesive plaster 2 or 2½ inches wide and about 5 or 6 inches long, the length varying with the size of the patient, is placed transversely across the extreme lower abdomen as nearly as possible to the pubes, the hair having been shaved clean for this purpose. To each end of this strip of adhesive plaster is attached a bandage of about the same width, long enough to reach around the body above the iliac crest, and be tied or otherwise fastened behind, or better, one end long enough to reach around and fasten at opposite end of plaster. If the ends of the plaster have a tendency to become loosened and pull up by traction of the bandage, this can be prevented by a narrow vertical strip across each end of the adhesive strap and applied to the skin above and below. The bandage itself is well padded with cotton, either folded within it or applied to the body immediately beneath it. This prevents any irritation of the skin from the bandage and permits of its being drawn as tightly as necessary in order to furnish the necessary support from below. If it is a little too tight, it can be easily adjusted and can be entirely relaxed at night if thought advisable, although I believe it is better to keep some support during the night as well as during the day. The great difficulty with the adhesive straps carried entirely around the body, is that if applied somewhat too firmly they cause irritation, and the difficulty of removal complicates their management very much. By means of this fixed point of support in the lowest zone of the anterior abdomen, the pressure is applied exactly where it should be and does the greatest possible good. Altogether, it has given me better results with less annoyance and is more easily managed than any mechanical appliance I have ever used.

Of course, a certain amount of irritation will be produced beneath the plaster in the beginning of treatment, its severity depending on the delicacy of the skin, but the occasional removal of the plaster, cleansing the skin, and using a dusting powder for twenty-four or forty-eight hours will entirely overcome it, and finally it can be used continuously. This can, of course, be done with the plasters applied according to the method of Dr. Rose. I have had incurable patients return after an interval of a year telling me that they were still unable to dispense with their adhesive straps and wore them very nearly continuously, leaving them off for a day or two at occasional intervals.



A device for the mechanical treatment of Glenard's disease. A indicates double-padded bandage; B, zinc oxid strip.

It cannot be too strongly emphasized that mechanical support is only an auxiliary in the treatment of splanchnoptosis. The fundamental defects in the musculature and other structures of the abdominal wall, the lack of tone in visceral supports, imperfect circulation and innervation, together with the neurasthenic state so often, I had almost said so constantly, associated, must all be taken into account and therapeutically met. The most brilliant results that I have obtained have followed about one month's treatment in the hospital, with massage, electricity, and such treatment of the digestive tract as the particular case requires, combined with and followed by a prolonged continuance of mechanical support, with correct living, suitable diet, etc. Many of these patients can be substantially cured in this way, even the kidney, which is, of course, usually greatly prolapsed, permanently occupying a much higher position, although it is very rare in my experience for the kidney to go back to its normal position.

In some few of these cases surgical treatment will be required, but it is surprising how many of them, even of the severer type, will yield to prolonged systematic treatment along the lines already indicated; and the very simple mechanical support above described, having the obvious advantage of costing but a few cents, thus making it applicable to all classes of patients, has proved of great assistance to me.

407 West Main Street.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

PANKREON. — Tannin-pancreatin-compound. — A mixture containing the active tryptic, diastatic and steatolytic ferments of the pancreas and about 8 per cent. of tannin.

It is obtained by the action of tannin on pancreatic substance.

Pankreon is a dry, grayish, odorless powder of a slightly acidulous taste. It is soluble in alkaline liquids and practically insoluble in water and acid liquids.

1 Gm. of pankreon digests in thirty minutes at least 50 per cent. of 100 Gm. of sodium caseinate dissolved in 4,000 Cc. of water.

Actions and Uses.—Pankreon has a tryptolytic, amylolytic, emulsifying and mildly astringent action. This action it is claimed is developed in the alkaline intestinal fluids, although a portion of the ferments is likely to be destroyed by the gastric juice during its passage through the stomach.

Pankreon is said to be useful in conditions of disturbed metabolism or anomalies of digestion due to functional inefficiency of the pancreas; in diarrhea, dysentery, dyspepsia, marasmus, etc.

Dosage.—For adults 0.25 to 1.0 Gm. (4 to 15 grains) and for children 0.06 to 0.25 Gm. (1 to 4 grains), three times per day.

Manufactured by the Chemische Fabrik Rhenania of Aachen, Germany. U. S. patents Nos. 685,543 and 695,254; U. S. trademark No. 36,268.

Therapeutics

TREATMENT OF POISONING

As the symptoms and treatment of poisoning are many times so similar, it seems best to divide poisons into classes, and then to describe the treatment of each class, rather than to multiply individual descriptions.

The following classification is of types of drugs. The individual drugs with references to the class to which they belong, and therefore to the treatment advisable, will be found in a table on another page.

Class 1.—Irritants of the Gastro-Intestinal Canal.
  - Acids.
  - Alkalies.
  - Irritant metallic salts.

Class 2.—Irritants of the Central Nervous System.
  - Atropin-containing drugs.
  - Caffein-containing drugs.
  - Cocain.
  - Scopolamin (hyoscin).
  - Strychnin.
  - Volatile oils.

Class 3.—Depressants of the Nervous and Circulatory Systems.
  - All cardiac drugs in large doses.
  - Coal-tar products.
  - Cyanids.
  - Hypnotics.
  - Narcotic drugs.
  - Nicotin.
  - Most phenol-containing drugs.

CLASS I.—IRRITANTS OF THE GASTRO-INTESTINAL CANAL

Most irritants in weak dilutions are astringent, while most astringents in strong solutions are irritant. The action of astringents and irritants on mucous membranes is, therefore, largely one of degree. Some astringents act chemically to form albuminates with the protein substance found on moist mucous membranes, thus coating and preventing the further irritation of the membrane. At the same time the blood-vessels of the membrane are contracted, the membrane is dried, and the secretion diminished. This is typical metallic astringent action. If this albuminate is insoluble or very slowly soluble in the media surrounding it the action just described is the only action due to the astringent, viz., there may be more or less pronounced irritation at first, but the after-effect is sedative. If, however, this albuminate tends to dissolve at its junction with the mucous membrane, the action of astringency is then continued and may become so irritating as to cause severe inflammation or with some metallic salts or acids cause ulceration and corrosion. Such drugs or preparations are called "gastro-intestinal irritants," and in poisonous doses will all produce the same immediate symptoms. Later individual symptoms or conditions develop due to the character of the substance absorbed, to its chemical nature and to the amount of local corrosion that it can cause.

Different metals have different powers of astringency and irritant action; also different salts of the same metal vary in the irritation which they will produce. The acid formed after the dissociation of the metallic ion decides the amount of irritation that the salt will cause. Also the greater the ease with which the metallic ion is dissociated from its acid ion the greater the corrosion; therefore, the soluble nitrates and chlorids are much more corrosive than the acetates, citrates and tartrates. The sulphates are between these groups in their irritant effect.

The most astringent metals in the order of their astringency are lead, iron, alum, copper, zinc and silver. The most astringent salt is lead acetate, while the most irritant salts are mercuric nitrate, mercuric chlorid and zinc chlorid. The sulphates and acetates of copper and zinc and the nitrates of sulphur and lead, if applied in weak solutions, are astringent, but are irritant if in large quantities or in strong solutions. Insoluble preparations of mercury may irritate and corrode, but insoluble salts of other metals are generally only astringent. Double salts of the metals are less likely to irritate, because they ordinarily do not precipitate albumin. A styptic strongly coagulates albumin, and hence causes a clot which stops hemorrhage.

Symptoms

The symptoms common to all gastro-intestinal irritants are irritation or corrosion of the mouth, throat and esophagus, depending on the concentration of the poison swallowed. Other symptoms are: more or less gastric pain; nausea; vomiting, first of the contents of the stomach, then of mucus, then often of blood; later diarrhea, first of the contents of the bowels, then mucus and, perhaps, blood are passed. There are more or less symptoms of shock due to the reflex action on the heart from irritation of the gastric branches of the pneumogastric nerve. The symptoms of collapse are a rapid, weak heart, dyspnea, cold surface of the body, clammy, cold perspiration, tendency to syncope, and a gradual failure of the pulse.

The symptoms of poisoning by gastro-intestinal irritants are:

Immediate Symptoms:

- Pain.
- Nausea.
- Vomiting.
- Colic.
- Diarrhea.
- Collapse.

Frequent After-Symptoms:

- Inflammation and ulceration of the mouth, throat and esophagus.
- Gastritis.
- Duodenitis (jaundice).
- Enteritis.
- Albuminuria.
- Nephritis.
- Ulceration, perforation, peritonitis.

Possible Remote Symptoms:

- Fatty degeneration of the liver, kidneys and heart.
- Strictures from the healing of the corrosions and ulcerations.

Treatment of Corrosive Poisoning

Immediate Treatment: Warm water drinks containing the antidote, if there is one (an emetic or a stomach-tube is rarely needed, and, if necessary, should be used with great caution and gentleness); albuminous and mucilaginous drinks, as milk, egg albumin, flaxseed infusions, slippery elm infusions, etc.; hypodermatic injections of morphin sufficient to stop pain and continued vomiting.

Treatment of Collapse: Rest, quiet; dry heat, especially to the region of the heart; atropin sulphate, 1/100 of a grain hypodermatically; strychnin sulphate or nitrate, 1/30 of a grain hypodermatically; repeated in three hours, if needed (large doses of strychnin are not advisable, as it cannot stimulate the heart or raise the blood-pressure as so long believed); camphor, a syringeful hypodermatically of a saturated solution in sterile olive oil (or a ready-prepared ampoule), every half hour for several doses; caffein as strong coffee, by rectal injection if there is no diarrhea.

After-Treatment: Give a saline purge, if deemed necessary. For acute gastritis give morphin sufficient to stop the pain, mucilaginous drinks, rectal alimentation. Give cardiac stimulants, if needed. Later give bismuth subcarbonate in large doses (2 grams or 30 grains) twice a day; later, a milk diet. Treat duodenitis and nephritis, if they occur. Order absolute rest in bed for one or two weeks, if the irritation or corrosion was severe, lest perforation from ulceration be precipitated. Treat ulcer of the stomach and strictures, if they occur.

CLASS II.—IRRITANTS OF THE CENTRAL NERVOUS SYSTEM

The principal symptoms of poisoning by drugs of this class are those of irritation of the central nervous system. There is restlessness and nervous excitement; there may be, later, delirium and convulsions, and, perhaps, still later, coma. The pulse is full, bounding, and generally rapid; there may even be delirium cordis or tachycardia. Respirations are increased in rapidity, the face is flushed and the skin of the body feels hot and dry, and there often is increased temperature. There may be vomiting; there often is diarrhea; there is vesical irritability, and often strangury, depending

TABLE OF SPECIAL SYMPTOMS AND SPECIAL TREATMENT OF VARIOUS POISONS

Name	Poison Class	Special Symptoms	Special Treatment	Remarks
Acetanilid	Class III	Cyanosis; lowered temperature.	Oxygen inhalations; artificial respiration; sodium bicarbonate.	Chronic poisoning causes anemia.
Alcohol (ethyl)	Class III	....	....	There may be acute delirium, in which case treat more as Class II.
Alcohol (methyl)	Class III	Often late unless dose is large.	Pilocarpin hydrochlorid in one-eighth gr dose is recommended; other treatment like Class III	More or less loss of vision by the third or fourth day.
Ammonia	Class I	May be swelling and inflammation of the bronchial tubes, hence dyspnea.	Diluted vinegar; lemon juice; olive oil; castor oil.	Stomach-tube contra-indicated.
Amyl nitrite	Class III	Respiratory and cardiac failure.	Artificial respiration; Trendelenburg position.	Treatment of poisoning by other nitrites similar.
Anilin	Class III	....	....	See treatment for acetanilid.
Antimony	Class I	Diarrhea soon occurs; late symptoms are those of Class III; circulatory depression.	Tannic acid, one-half teaspoonful, in water; later magnesium carbonate	If much of the poison has been absorbed, fatty degeneration of the organs may develop.
Antipyrin	Class III	Profuse sweating; lowered temperature.	Sodium bicarbonate	See acetanilid.
Arsenic	Class I	Frontal headache; constriction of the throat; colicky pains; eruptions on the skin.	Official antidote, ferri hydroxidum cum magnesii oxido, 3 oz.; later castor oil.	Renal inflammation is a frequent sequence.
Atropin	Class II	Flushed face; dilated pupils; dry throat; rapid heart.	Tannic acid; morphin in not too large doses as a partial physiologic antidote	Catheterize the bladder.
Belladonna	Class II	....	....	See atropin.
Bromids	Class III	....	....	Treatment similar to chloral.
Caffein	Class II	....	Dry heat to the body	....
Camphor	Class II	....	....	....
Cannabis indica	Class II	....	....	....
Cantharides	Class I	Kidney and bladder irritation; strangury; abortion.	....	....
Castor oil beans	Class I	Collapse.	....	....
Carbolic acid	Class III	....	....	See phenol.
Chloral	Class III	Pupils dilated; coma	....	Inhalations of oxygen; artificial respiration; dry heat; Trendelenburg position.
Cocain	Class II	Pupils dilated; often rapid heart; often cyanosis.	Tannic acid if the drug has entered the stomach.	If collapse, Trendelenburg position; if respiratory failure, oxygen and artificial respiration.
Codein	Class III	....	....	See morphin.
Creosote	Class III	....	....	See phenol.
Chromic acid	Class I	Often cramps in the legs	Chalk; lime water; magnesia	Correct name, chromium trioxid.
Cyanids	Class I and III.	May act like hydrocyanic acid; may cause stomach symptoms.	....	See hydrocyanic acid.
Digitalis	Class III	The cerebrum not much affected.	Tannic acid; nitroglycerin hypodermatically.	....
Ergot	Class III	Pupils dilated; cold surface of the body; circulatory depression.	Alcohol; nitroglycerin	....
Formaldehyd solution.	Class I	....	If swallowed, very weak solutions of ammonia; diluted aromatic spirits of ammonia.	If inhaled or taken in strong solution, danger of edema of the glottis.
Gelsemium	Class III	....	....	....
Hydrochloric acid.	Class I	Lips and mouth show white eschar.	Lime water; magnesia	Emetics and stomach-tube should not be used. Chalk and alkaline carbonates should not be given.
Hydrocyanic acid.	Class III	Odor of almonds; respiration and heart fail immediately.	Patient on back with feet raised; artificial respiration; ammonia inhalations; camphor and atropin injections; wash stomach with stomach tube.	....
Hyoscyamus	Class II	....	....	See atropin.
Iodoform	Class II and III.	May be symptoms of nervous excitation, with fever; later, prostration.	....	....

TABLE OF SPECIAL SYMPTOMS AND SPECIAL TREATMENT OF VARIOUS POISONS—*(Continued)*

Name	Poison Class	Special Symptoms	Special Treatment	Remarks
Lead acetate....	Class I........	Colic; muscle cramps; convulsions; stupor; coma.	Dilute hydrochloric, a teaspoonful well diluted; magnesium or sodium sulphate 30 grams (1 ounce).	Later, multiple neuritis.
Lobelia	Class III......	....	....	....
Matches	Class I.......	....	....	See phosphorus.
Mercuric chlorid (corrosive sublimate).	Class I.	Convulsions; coma; collapse...	Raw eggs and albumin water..	Late symptoms are salivation; nephritis; multiple neuritis.
Morphin	Class III......	....	....	See opium.
Muriatic acid ..	Class I.	....	....	See hydrochloric acid.
Nicotin	Class III......	....	....	See tobacco.
Nitric acid.. .	Class III......	Mouth and lips may be stained yellow.	....	See remarks under hydrochloric acid.
Nitroglycerin .	Class III......	....	....	See amyl nitrite.
Opium	Class III......	Pupils contracted; respiration slowed.	Tannic acid; atropin; wash stomach with potassium permanganate solution 1 part to 1,000.	Catheterize the bladder and wash out stomach frequently; artificial respiration as long as heart continues to beat.
Oxalic acid.....	Class I	Depressed circulation; cyanosis.	Magnesia; chalk; later, magnesium sulphate as cathartic.	Alkalies and alkaline carbonates are contra-indicated.
Paraldehyd	Class III......	....	....	....
Phenacetin	Class III......	Lowered temperature........	Sodium bicarbonate...........	See acetanilid.
Phenol	Class III......	If solution is strong, white eschar on lips and mouth; collapse; coma; urine black after standing.	Dilute alcohol 1 part to 4, or clear whisky or brandy; sodium sulphate in solution.	Avoid all oils and fats.
Physostigma....	Class III......	Pupils contracted; may cause vomiting and purging.	....	....
Physostigmin (eserin).	Class III	....	Tannic acid. Strychnin is a physiologic antidote.	See physostigma.
Phosphorus	Class I.......	Breath smells garlicky. Most serious symptoms sometimes slow in developing.	Use copper sulphate as emetic; wash stomach with 1-1,000 potassium permanganate solution. Later, magnesium sulphate.	Avoid all oils. If much absorption, likely to cause serious liver and kidney inflammation.
Pilocarpin	Class III......	....	Tannic acid; atropin hypodermatically.	....
Potassium chlorate.	Class I.......	....	....	Nephritis a frequent sequela.
Potassium hydrate.	Class I....	....	....	See ammonia.
Prussic acid....	Class III.....	....	....	See hydrocyanic acid.
Ratsbane	Class I.....	....	....	See phosphorus.
Resorcin	Class III	....	....	See phenol.
Rough-on-rats ..	Class I.	....	....	See arsenic.
Salicylic acid...	Class II....	....	....	If taken in concentrated form, treat stomach as in Class I.
Salol	Class III......	....	....	See phenol.
Santonin	Class III......	....	....	May be delirum and convulsions.
Scopolamin (hyoscin).	Class II and III.	May act like atropin, but may cause serious circulatory depression.	....	See atropin.
Silver nitrate...	Class I.......	....	Sodium chlorid (table salt solution).	....
Sodium hydrate.	Class I	....	....	See ammonia.
Stramonium ...	Class II......	....	....	See atropin.
Strophanthus ..	Class III......	....	Nitroglycerin....	....
Sulphonal	Class III......	May cause ptosis, suppression of the urine, and papular skin eruptions.	Sodium bicarbonate; later, magnesium sulphate.	Treatment quite similar to acetanilid.
Sulphuric acid..	Class III......	Lips and mouth may show black eschar.	....	See remarks under hydrochloric acid.
Tobacco	Class III......	Prostration	Tannic acid if tobacco or nicotin has been swallowed.	Trendelenburg position.
Trional	Class III......	....	....	See sulphonal.
Veratrum	Class III......	....	....	See aconite.
Veronal	Class III......	....	....	See sulphonal..

on the drug. Some drugs of the atropin series may cause vesical paresis. There are muscular twitchings; there may be cramps; and, as above stated, convulsions may occur. The pupils are of course dilated if the poisoning is by any member of the atropin series or by cocain, and they often become dilated during cerebral excitement from other members of this group.

The symptoms of poisoning by irritants of the central nervous system are:

Immediate Symptoms:

- Gastro-intestinal burning and pain, perhaps nausea and vomiting, if the poison contains an aromatic or volatile oil.
- Cerebral excitement.
- Rapid heart.
- Rapid respiration.
- Erythemas and flushing of the face and surface of the body.

Frequent After-Symptoms:

- Purging.
- Frequent urination.
- Muscular twitchings.
- Delirium.
- Convulsions.
- Coma.
- Failure of the circulation.

Possible Remote Symptoms:

- Abortion in pregnant women.
- Albuminuria and nephritis if the poison is a renal irritant as are many of the volatile oils.
- Prolonged sleeplessness and nervous irritability.

Treatment of Poisoning by Irritants of the Central Nervous System

Administer warm water with the antidote, if there is such.

Give an emetic. The emetics in the order of their strength are: mustard (a tablespoonful in a glass of warm water); ipecac (2 gm. [30 grains] of powdered ipecac, or a tablespoonful of the syrup); zinc sulphate (2 gm. [30 grains] dissolved in water); copper sulphate (0.50 gram [7½ grains] dissolved in water); apomorphin (1/10 of a grain given hypodermatically). Any of these emetics may be repeated in fifteen minutes if there is no satisfactory result. It should be remembered that apomorphin is depressant to the circulation.

Wash out the stomach by means of a stomach-tube if there is no satisfactory emesis. If the vomiting is satisfactory, continue to administer warm water until the stomach washes clean.

Administer one or more nerve sedatives. The best are bromids and chloral, and the dose depends on the character of the poison. They are best administered by the rectum, at least provided nausea and vomiting is continued after the stomach has been cleared of the poison. If there is much circulatory depression, the best sedative to administer is morphin, hypodermatically, perhaps combined with scopolamin (hyoscin). An adjunct to the action of the morphin as a central nervous sedative and as a strengthener of the circulation is ergot, given intramuscularly. If there are convulsions, inhalations of chloroform are required.

Apply dry heat to the body, if the surface is cool or there is a tendency to collapse.

If heart failure occurs later in the poisoning, from shock or from the depression caused by nausea, such circulatory stimulants should be given as camphor (a saturated solution in olive oil); strophanthin (given hypodermatically or intravenously in a dose of 1/500 of a grain); epinephrin (adnephrin, adrenalin, adrin, supracapsulin, suprarenalin) in aseptic ampoule or 1 c.c., 15 minims, of a 1 part to 10,000 solution; or intramuscular injection of some aseptic ergot preparation (1 ampoule) and repeat in an hour, if needed.

Give plenty of water with a demulcent, if there has been irritation of the stomach either from a volatile oil poisoning or from the emetic used.

CLASS III.—DEPRESSANTS OF THE NERVOUS AND CIRCULATORY SYSTEM

The symptoms of poisoning by drugs of this class are, as their name implies, those of circulatory and nervous depression. The pulse is either slow or rapid, but generally weak; the surface of the body generally becomes cold; respirations are slowed; pupils are generally dilated unless the poison is morphin or nicotin; often the patient becomes faint; drowsiness soon develops, and if a narcotic has been taken stupor soon develops; perhaps convulsions will occur; later paralysis and coma.

Immediate Symptoms (if the poison is a depressant of the nervous system):

- Depression.
- Drowsiness.
- Slow, weak pulse.
- Slowed respiration.
- Paralysis.
- Coma.

Later Symptoms:

- Muscular weakness.
- Circulatory weakness.

Immediate Symptoms (if the poison is a circulatory depressant):

- Rapid or slow, weak pulse.
- Cardiac anxiety.
- Cold, clammy perspiration.
- Face pale.
- Perhaps convulsions.
- Syncope.

Treatment

Wash out the stomach (emetics or stomach-tube, as see above).

Administer not only the chemical, but a physiologic antidote, if there is such.

Apply dry heat to the body.

If the poison was a narcotic, give cerebral and nervous stimulation, as caffein (coffee), camphor, atropin, strychnin.

If the poison was a circulatory depressant, give atropin, ergot, epinephrin or strophanthin, as above described.

Compel prolonged mental, circulatory and physical rest.

The accompanying table is arranged alphabetically.

The second column gives the class to which the poison belongs, and the treatment for this class has been given under the headings of the general treatment for each class. Therefore the number of the class to which the poison belongs refers to the treatment there outlined.

Column 3 ("special symptoms") suggests symptoms of poisoning which are characteristic of the drug, such symptoms being in addition to those which are characteristic of the class of poisons to which the drug belongs.

In the fourth column ("special treatment") is indicated any chemical or physiologic antidote that is valuable in treating poisoning by the drug, and is in addition to the general rules discussed above.

HUGHLINGS JACKSON AND NEUROLOGY

He who stimulates others to work, who unfolds a new idea, discusses a new relation between facts, or brings together a mass of hitherto uncorrelated observations, and puts them in usable form for the multitude—he is a great man. Modern commerce and applied science have been the direct result of the work of such men, but in no field are there required mental qualities of such high order as in medicine.

To wrest from the future secrets that will serve mankind requires a constructive imagination that visualizes, as though through a telescope, the hitherto unseen, combined with attention to microscopic detail and acuteness in analysis. These qualities, though rarely found combined in one mind, were realized in one of England's greatest physicians, whose death is recorded by our London correspondent.[1]

The name of John Hughlings Jackson, known all over the world through the term "Jacksonian epilepsy," stood for infinitely more than nomenclature. He has been the founder, the creator, the inspiration of English neurology for at least forty years. As far back as 1877, he had established the fact that "the cerebellum is the center for continuous movements, and the cerebrum for changing movements," and on the doctrine of the tonic nature of cerebellar activity thus established, he worked till his death. Four decades ago he defined apraxia. He gave us our knowledge of temporosphenoidal disease, of double hemiplegia, and of many of the more important manifestations of epilepsy.

He began the study of the nervous system and its diseases at a time when all knowledge concerning the subject was fragmentary and empirical. Bringing to bear on this scattered disconnected material a mind, which, as one of his contemporaries said, "combined singular acuteness in analysis with a remarkable power of philosophic thought, and wide generalization," he slowly and surely worked out the true principle of localization of function in the nervous system. To us the idea of brain localization is as familiar as that of the circulation of the blood; it is hard for us to realize that even in the latter half of the last century the only idea of cerebral localization was that which the phrenologists had distortingly adopted from the teachings of Gall and Spurzheim.

When Jackson began to study cases of nervous diseases, the French physiologic school was brilliantly to the fore. Yet as a young man he wrote: "I should be misunderstood if I were supposed to underrate the physiological study of disease of the nervous system. Indeed, I think its neglect shows want of education, but to neglect the clinical shows want of experience and sagacity. Never forget that we may run the risk of being overeducated, but undercultivated."

Jackson was the greatest scientific clinician in neurology of the nineteenth century in England. The whole of the material from which he drew his conclusions was found in the wards of a hospital. He never performed an experiment, yet he has influenced the course of neurologic medicine more profoundly than has any other one observer. Each patient was to him an example of some disturbed process, and helped to elucidate the law of normal and morbid functions. The field of his great work was the National Hospital for the Paralyzed and Epileptic, Queen's Square, where he was actively at work for forty-four years, and the London Hospital, where he served for thirty years.

The titles of the papers he published, which in 1895 filled five quarto pages, in double column, in the *London Hospital Gazette*, form in themselves a history of the growth of neurology under his compelling genius. Much of his writing that sounded obscure when published has borne fruit in the work of later neurologists; for he divined, or perceived prophetically, from his rich experience, much that has required years of patient experiment to prove. The full anatomic demonstrations of Dr. Jackson's theories and discoveries have been published only in the last four or five years; but bit by bit, from all parts of the world, have come corroborations of his outlines, and fruits ripened under another's care from the seed he so generously gave. Perhaps it is because of his extreme modesty and retiring nature, as well as the abstract nature of his studies, that even in his own country the public has not known him as one of its greatest men: but he belongs to that brilliant group which included Darwin, Huxley, Tyndall, Galton and Spencer, the latter being his warm personal friend.

He inherited his energy, courage and caution from his father, and his tender, affectionate and constant nature from his mother; but his mental stimulus, he was wont to say, came from the lectures of Sir James Paget, who was in his zenith as a teacher in Dr. Jackson's student days.

Although he was childless, his love of children was great. His quiet humor used to charm his students. He would at the end of one of his illuminating lectures caution them not to take him too seriously, as he was only a "Bedlamite theorist." It was he who after an operation in trephining expressed his regret that the opportunity of putting a joke into a Scotsman's head had been let slip.

---

[1] Page 1467

Jackson's friends compared his genius to that of Samuel Johnson, but the great neurologist was gentle and polished, whereas the great lexicographer was rude and bearlike. Jackson's resemblance to his prototype was displayed, however, in his power of brushing aside all subterfuges, and going to the very essence of the matter. His was an exceptionally well-rounded character; it is a rare personality that we are resigning to the past.

HYGIENE AND RACE STAMINA

The larger effect of hygienic measures is a question which presents many moot points. From a humanitarian standpoint no one questions the duty of safeguarding by every means within the power of science the lives of the population and especially the infant population. From the standpoint of physical race betterment, however, many regard hygiene and sanitation as of doubtful or negative value, since these measures allow the weak to live and perpetuate their kind. Assuming that in a considerable proportion children who succumb to bad hygiene and defective food are inherently weak—a theory by no means universally admitted—it would be conceded that if they were aided in reaching a maturity which must be more or less defective they would transmit their weaknesses to their descendants and thus contribute measurably to the deterioration of the race as a whole. An attempt to show how this works out under actual existing conditions as between the Chinese and the western white population has been made by Prof. E. A. Ross.[1]

Ross says that, on account of lack of good hygienic conditions in China, out of ten children born, the three weakest will die in infancy and five others will probably fail to grow up, while in our own country, out of the same number of children born, only three will fail to reach maturity. This would seem to favor better hygienic conditions for the betterment of the race, yet Ross feels that there may be some doubt on this point. For, of the seven surviving, the five corresponding to the five additional Chinese who die, will, according to hypothesis, be weaker in constitution and will transmit their weaker qualities to the offspring; while the two surviving Chinese are the hardiest of the lot and will transmit their hardy qualities to their offspring, thus in the end increasing the general stamina of the race.

In order to test this idea, Ross closely questioned thirty-three physicians practicing in various parts of China, chiefly in missionary hospitals. Twenty-nine were positive that the Chinese physique evinces superiority in some respects over that of the white people of the western world. It has been found that surgical shock is rare among the Chinese, that they endure surgical operations well and recover from them, from most serious injuries and from septic conditions in an astonishing manner. They also stand higher degrees of fever, are more resistant to pus-producing germs and are very tolerant of pain, while fewer Chinese women die from puerperal fever. This applies particularly to the lower classes, who live among the most unhygienic surroundings. The percentage of recoveries in the poorly-equipped hospitals from the gravest injuries and operations equals or exceeds that under the ideal conditions of the best-equipped hospitals of Berlin or Vienna. This indicates a strong and abiding race vitality and it may reasonably be assumed that it is a direct result of the survival of the strongest, or at least most enduring, members of the race. In other words, the selective process imposed by unfavorable surroundings, has established in the Chinese a higher degree of immunity to conditions inimical to survival.

The deduction would seem to be that the way to produce a strong race well endowed with vital qualities would be for that race to multiply to excess, and then to undergo murderous reduction by exposure to disease and unhygienic conditions. A second consideration shows that this process has its drawbacks. While under poor or bad conditions the Chinese will outdo the white man, under good conditions the latter rises to a higher level of efficiency. The Chinese, who can underlive, cannot outwork the white man under the white man's conditions. In short, the low-caste Chinese seems to illustrate very well an often misapprehended fact, namely, that the survival of the fittest is not necessarily the survival of the best, the most efficient, or even the strongest; it is simply the survival of those best fitted to survive in that particular environment—and not necessarily well fitted for any other environment. Those who are fittest for a white man's environment are less fit for that of the Chinese, and vice versa. The fitness of the low-caste Chinese is fitness to endure existence on the lowest terms. On the evidence so far presented, we may dismiss the case against hygiene as an agency in the deterioration of the race with a Scotch verdict—not proven.

THE DEFENSE OF THE ORGANISM AGAINST TUBERCULOSIS

The investigations of Calmette and Guérin[1] on experimental tuberculosis have yielded certain interesting and novel results. Their investigations began with the study of the modifications of the tubercle bacillus during its passage through the digestive tract. This led to the study of a series of cultures of tubercle bacilli on potato in 5 parts beef-bile to 100 parts glycerin. A single passage on this medium increased the virulence of the bacillus very much for the guinea-pig, but, on the other hand, successive cultures led to progressive attenuation of virulence. The bacilli cultivated in the manner indicated possessed the same variations in virulence for cattle as for guinea-pigs; in cattle intravenous injection produced a febrile disease which rarely terminated fatally and in the course of which no tubercles were formed in any of the organs. A number of animals were vaccinated with increasing doses of bile bacilli, some receiving as much as 200 mg. of bacilli intravenously; of these animals, some became very cachectic, but when they were slaughtered not the faintest trace of any tuberculous lesions could be found.

---

[1] Ross, E. A.: The Race Fiber of the Chinese, Pop. Sc. Monthly, October, 1911, p. 403.

[1] Calmette and Guérin: Ann. de l'Inst. Pasteur, 1911, xxv, 625.

The serum of animals which had been treated in this way was examined as to its effects on tuberculous infection in guinea-pigs and cattle. This serum was strongly agglutinating for tubercle bacilli and caused an abundant precipitate with tuberculin. In the guinea-pig the serum did not exercise any preventive or curative action. On the other hand, it seemed to hasten the development of the lesions. In cattle the results were somewhat different. While the serum did not seem to possess any immunizing or bactericidal power, even in large doses, it caused, when injected together with bile bacilli, more rapid elimination of the bacilli by the liver and intestines than usually takes place.

It was also found that the immunized animals eliminated not only the attenuated bile bacilli, but also virulent bacilli, the latter also passing through the organism without causing any tuberculous lesions. It has been noticed before that tuberculous cattle eliminate bacilli with greater rapidity than do normal animals. The general conclusion is reached that the more or less well-marked resistance to tuberculosis produced in cattle by means of diverse methods of vaccination depends on the power acquired by the organism to eliminate tubercle bacilli by way of the liver and the intestines. So long as this condition exists the tubercle bacilli do not behave as active parasites, but more like simple, inoffensive, foreign bodies.

One may regard these phenomena as another expression of the fact that the tuberculous organism possesses considerable resistance to reinfection, but the exact mechanism involved is not yet clear and presents problems for further investigation.

TYPHOID FEVER AND THE WATER OF THE GREAT LAKES

The rapid growth of cities on the Great Lakes in the United States and Canada has raised many problems for the sanitarian. It is natural that these cities should seek to obtain their water-supply from the great bodies of fresh water close at hand. It seems to have been equally natural that they should attempt to dispose of their sewage by discharging it into the lake, thus effectually preventing a nuisance by simply diluting the sewage with a large volume of oxygen-containing water. So far as the avoidance of offense to the senses is concerned this method of sewage disposal appears in most cases to have been eminently satisfactory. Not so much can be said on the sanitary side. There is evidence that even in the case of small towns and cities this practice has been accompanied by an excessive amount of typhoid fever, while in the larger cities like Chicago, Cleveland, Milwaukee and Toronto it is a familiar fact that water-borne typhoid fever has been at times a veritable scourge.

Many of the cities so situated have attempted to avoid contamination of the drinking-water with sewage by extending the water intakes far out into the lake. For a time such an expedient usually proves efficacious and a reduction in water-borne disease is noted. After a longer or shorter period, however, the increasing volume of sewage due to increase in population again makes itself felt by an alarming contamination of the water at the intakes, and eventually typhoid fever again reaches a high point. Some few cities are so placed topographically that they can take advantage of favorably situated bays or points of land to divert the flow of sewage away from the water intakes and so, it is hoped, lessen pollution of the water-supply. In some cases also there has been a misplaced reliance on prevailing winds or currents for keeping the sewage away from the drinking-water source. Exact observations with floats and bacterial tests have now shown that neither winds nor currents, nor yet local topography, can be altogether depended on to prevent occasional contamination.

The experience of practically all the large cities on the Great Lakes has followed the lines indicated above. Detroit, to be sure, has suffered less than many others because of its ability to discharge its sewage into the Detroit River at a point below its water intakes. There is, however, danger of contamination from the considerable population draining into Lake St. Clair above the intakes, and at least one serious epidemic of typhoid fever in Detroit has been attributed by high authority to water infection. Other cities have fared even worse. The city of Erie, where for years the typhoid death-rate has been very high, experienced only last winter an extremely severe explosive outbreak of water-borne typhoid fever, over 750 cases being reported in January and February, 1911. Very recently in Cleveland, Buffalo and Milwaukee, concern has been expressed over the gravity of the local situation and in some cases disinfection of the water-supply with hypochlorites has been carried out.

In view of the well-recognized danger which hangs over some of the most flourishing of our American cities the studies set on foot by the Public Health and Marine-Hospital Service on the sewage pollution of interstate and international waters are to be warmly welcomed. The first section dealing with Lake Erie and the Niagara River has lately been published.[1] Ample illustration of the conditions we have cited will be found in its pages and the publicity there given to facts long known to students of public health, should do much to stimulate action. Even if in some cases the writer's conclusions are too hasty, as appears in the case of Toledo, the mass of data contained in this report will be of great value in inducing expert study of local conditions. The conditions under which water-borne typhoid fever occurs in the cities on the Great Lakes appeal to the imagination of the average citizen, and we cannot believe that the "endless chain" of typhoid bacilli passing into the sewers and back again through the water-pipes will be allowed to continue unbroken.

Current Comment

ACTIVE IMMUNIZATION IN DIPHTHERIA AND OTHER DISEASES

While the discovery of diphtheria antitoxin by Behring has served to revolutionize our attitude toward this much-dreaded disease, the use of antidiphtheric serum for protective purposes is not altogether satisfactory. It is possibly owing to deficiency of antibacterial powers in antidiphtheric serum that its prophylactic administration is not of more prolonged effect and sometimes even without any effect. Blumenau[1] reports the occurrence of nineteen cases of diphtheria in 348 persons who had been given the usual prophylactic treatment, the infection in several cases following two, and in one instance three, preventive doses of serum. In view of this large proportion of failures, he was led to investigate a method of active immunization against diphtheria originally proposed by Dzerjgowsky, and his results are sufficiently striking to deserve attention. It had been previously shown that the repeated subcutaneous injection of very minute doses of toxin could produce a relatively high antitoxic power in the human being, and Dzerjgowsky found that equally good results followed the application of toxin to the nasal mucosa by tampons. Blumenau used this method with seven children, and with sufficiently numerous applications he was able to raise the antitoxin content in one case to ten units per cubic centimeter, or to 1,000 times its former value. The rise in other cases was not so marked, but in all it compared favorably with, and in several instances surpassed, the antitoxic power of several individuals who apparently possessed a high degree of natural immunity. As to the permanency of the protection so acquired, data are lacking for the human being, but from results in lower animals it should be of considerable duration as compared with the very transient passive immunity conferred by the use of antitoxic serum. If Blumenau's results are supported by further work, however, the method may be found to have, as he points out, great applicability in the wholesale prophylaxis in institutions in which large numbers of children are habitually aggregated. At all events an effective, simple method of active immunization for prophylactic purposes is desirable in order to limit as much as possible the spread of diphtheria. The success of protective inoculations against typhoid is established. Now that we definitely know that the cause of measles is present in the blood in the early stages of the disease, a convenient source of the virus, whatever its nature, being available, it does not appear impossible that a method of protective inoculation against this disease may be devised. And as to scarlet fever, the demonstration by Koessler[2] that the lymph-nodes harbor a specific antigen or virus of unknown nature, furnishes a basis for the hope that new methods of protection against even this disease soon will be proposed and tried.

ELIMINATE THE TERM "ALLOPATH"

Elsewhere in this issue[3] we reproduce some correspondence between a committee representing the Fulton County (Ga.) Medical Society and the publishers of a city directory. The committee protests against the classifying of non-sectarian physicians as "allopaths." We commend the action of this Georgia society to societies all over the country, and especially to practitioners who permit themselves to be called, or who call themselves "allopaths."

SUCCESS OF COLD STORAGE IS NO GUARANTEE OF THE QUALITY OF COLD-STORAGE FOOD

In Chicago recently a banquet was given for which the menu was prepared from food which had been in cold storage for many months. The object of the banquet was to prove that food, even though stored for a long time, is both healthful and palatable. It only proved that some food may be palatable and harmless after such storage. The extensive publicity given to this banquet and its object by the energetic press bureau of the cold-storage people was therefore a very amusing feature. We are not aware that anyone has ever denied that, when properly handled and surrounded by the necessary conditions, food can be kept in cold storage in a fairly acceptable condition for comparatively long periods of time. If this banquet committee could not find, and if the public did not find, some acceptable food from among the millions of dollars' worth of ancient materials in the various warehouses, the cold storage of food products as a business would have been terminated long ago on account of financial failure. Cold storage is a good thing. It has been used, in a crude way, in country cellars and spring houses for generations. Its modern development has added immensely to the possibilities of our tables, but like many other good things, it is frightfully abused. In order to get good results, one must have good material to store, and must be able to prevent harmful changes during storage. The condemnation by governmental authorities of millions of pounds of cold-storage food shows the defects of the actual system in at least one respect. It is only by the constant vigilance of health officials that greater and more dangerous abuses are prevented. The employment of cold storage as a means of wresting unrighteous profits from the public, by buying large quantities of food products when cheap and plentiful and retailing them at higher prices when scarce, is another serious abuse, which, however, affects the pocket-book rather than the health of the people.

---

[1] Blumenau: Jahrb. f. Kinderh., 1911, lxxiv, 141; abstr. in THE JOURNAL, October 14, p. 1328.

[2] Koessler: Jour. Infect. Dis., 1911, ix.

[3] Page 1473.

The fact that the banqueters found the food palatable and survived seems to us to be beside the point. If a banquet such as this had been made an adjunct to a campaign for preventing the abuse of cold-storage methods, for limiting them to their legitimate field and for perfecting the methods of handling food products, more would have been accomplished by the cold-storage people in overcoming the prejudice of the public and in popularizing cold-storage goods.

LIABILITY FOR OBLIGATIONS OF OTHERS MUST BE IN WRITING

In the Medicolegal Department of this issue,[1] appears an abstract of the decision of the Supreme Court of Oklahoma which is of practical interest to physicians. The testimony showed that the defendant asked the plaintiff, a physician, to go to see the wife of his tenant and added "I will see that you are paid." The court says that "the question was whether . . . the credit was given solely to the defendant or to the husband of the woman . . . with the understanding that if the husband did not pay the charge then the defendant would. If the former, that is, if the defendant's liability was primary, such verbal contract was valid and the defendant was liable. But if the intention was that the husband should be primarily liable and that the defendant's liability should be only collateral . . . then the contract was void as within the statute of frauds which requires promises to answer for the debts of others to be in writing." To put the language of the court in every-day terms: If A says to a physician, "Go and take care of B and I will see that you are paid," this constitutes a direct contract between the physician and A, and an oral agreement to this effect is valid and will be sustained by the courts. But if A says to the physician, "Go and take care of B and, if he does not pay you, I will," such a statement is the assumption by A of an obligation primarily incurred by B, and is not legally binding on A, unless made in writing, as the oral assumption of the obligation of another is not binding. The practical application of this important distinction is obvious. When professional services are rendered at the request of a third party from whom the physician expects to secure his compensation, either such agreements should be in writing or it should be plainly understood that the third party assumes the direct primary liability for the services rendered.

Medical News

DELAWARE

State Society Meeting.—The 122nd annual meeting of the Delaware Medical Society was held in Lewes, October 9-10, and the following officers were elected: president, Dr. Frank L. Springer, Newport; vice-presidents, Drs. Roland G. Paynter, Georgetown, and James L. Crossmore, Wyoming; secretary, Dr. George W. K. Forrest, Wilmington (reelected); treasurer, Dr. Samuel C. Rumford, Wilmington; councilor: Dr. James Beebe, Lewes; trustee of the *Delaware State Medical Journal*, Dr. George Frank Jones, Georgetown; editor, Dr. Albert Robin, Wilmington; delegate to the American Medical Association, Dr. Hiram R. Burton, Lewes, and alternate, Dr. Luther S. Conwell, Camden. Wilmington is the next meeting-place.

IDAHO

State Medical Association Meeting.—The Idaho State Medical Association held its ninth annual meeting in Boise, October 11-13, under the presidency of Dr. John W. Givens, Orofino, and elected the following officers: president, Dr. William F. Howard, Pocatello, and secretary-treasurer, Dr. Edward E. Maxey, Boise (reelected). The association pledged itself to work for the establishment of a state sanatorium for the treatment of tuberculosis, and for medical inspection in the public schools. The next meeting of the association will be held at Portland, where it will meet with the state associations of Oregon and Washington, under the head of the Northwest Tri-Medical Association.

ILLINOIS

Personal.—Dr. Nathaniel T. Stevens has been appointed local surgeon of the Illinois Central System at Clifton.——Dr. Frank R. Pitner, Clay City, said to the the oldest practitioner of Illinois, celebrated his 99th birthday anniversary, October 16.

Chicago

***Tag Day.**—The annual "Tag Day" for children, October 16,* resulted in contributions of $60,000, which is to be divided among the various hospitals and institutions for children of the city.

Personal.—Dr. Max Thorek has been appointed a member of the consulting staff of Cook County Hospital.——Dr. Mary B. White has been appointed a member of the Board of Visitors of County Institutions.

Surgical Society Election.—At the annual meeting of the Chicago Surgical Society, October 20, Dr. Frederick A. Besley was elected president; Dr. Samuel C. Plummer, vice-president; Dr. Allan B. Kanavel, secretary, and Dr. Dean D. Lewis, treasurer.

Favors Sanitarium Plans.—Informal approval of the plans for the municipal tuberculosis sanitarium was voted by the city council committee on finance, October 13. The cost of the proposed group, including lighting and sewerage, is estimated at $818,000. This will provide for 350 patients and administrative facilities. The intention is evidently to accommodate 500 patients. A site has already been purchased by the city at a cost of $158,000.

IOWA

Southeastern Physicians to Meet.—The thirty-sixth annual meeting of the Southeastern Iowa Medical Society will be held in Washington, November 16, under the presidency of Dr. Clyde A. Boice, Washington.

Drake Alumni Clinic.—The Drake Medical Alumni Association, by a special committee, is arranging for a special two-day clinic to be held at the university in Des Moines next spring. The committee consists of Drs. Charles F. Smith, Wilbur S. Conkling, Robert P. Parriot, Elmer B. Mountain, Des Moines, and Dr. George F. Jenkins, Keokuk. Invitations are to be sent to all the alumni, and the aim is to make it a brief, practical course in surgery, medicine and laboratory work.

Personal.—Dr. Charles E. Ruth, who recently returned from Ponce, Porto Rico, has located in Des Moines.——Dr. Albert A. Anderson, Des Moines, is reported to be seriously ill with septicemia due to a wound of the right hand.——Dr. John V. Littig has been appointed medical inspector of the public schools of Davenport.——Dr. Charles H. French, Cedar Rapids, is reported to be seriously ill with septicemia in St. Luke's Hospital.——Dr. Robert H. Sutton, Shenandoah, was recently presented with a gold-headed cane by the Page County Medical Association, on the occasion of the fiftieth anniversary of his entrance into medical practice.

MARYLAND

Baltimore

Medical Faculty Meeting.—The semi-annual meeting of the Medical and Chirurgical Faculty of Maryland was held at Baltimore, October 20. The principal address was delivered by Dr. Harvey W. Wiley. There were clinics and luncheons at the various hospitals and demonstrations at the Pasteur Institute. Dr. William H. Welch announced that Dr. Oliven of Germany was in Baltimore making arrangements for a large delegation of German physicians, who are coming to America to attend the International Congress of Hygiene and Demography in Washington, September, 1912. They are to be entertained in Baltimore before going to Washington. A report was submitted, favoring the establishment of a state colony to which alcoholic patients may be committed directly, without the necessity of criminal proceedings.

---

[1] Page 1478

Typhoid Vaccination at Johns Hopkins Hospital.—Johns Hopkins Hospital is offering to its doctors, nurses, students and employees, the privilege of being vaccinated against typhoid fever, and many are availing themselves of the opportunity.

Personal.—Dr. William H. Welch has consented to open the bazar *for the Home of Orphans and Widows of Physicians*, November 1.——Dr. Edward C. Bubert is reported to be ill at his home.——Dr. Rupert Norton has been elected president of Johns Hopkins Hospital Medical Society.——Dr. James A. Fechtig is convalescent after an operation for appendicitis.

MASSACHUSETTS

Decision Against Health Board.—Judge Brown of the Superior Criminal Court at Salem is said to have rendered a decision October 18 that a city board of health has no power to make and enforce a rule that fruit exposed for sale shall be *covered from* the dust.

Ask Walcott's Reappointment.—More than 2,000 signatures of physicians were on the petition which Dr. Frederick C. Shattuck, Boston, presented to Governor Foss, October 13, asking for the reappointment of Dr. Henry P. Walcott, Cambridge, on the Metropolitan Water and Sewerage Commission. Dr. Walcott, whose term expired on March 20 last, has been a member of the commission since its establishment in 1895, and chairman of the State Board of Health since 1886.

Ether Day.—Ether day was observed October 16 at the Massachusetts General Hospital in Boston by the usual clinics and luncheon. In the afternoon Dr. Simon Flexner gave an address on "The Biologic Basis of Specific Therapy." The alumni met for a banquet in the evening and were addressed by Drs. Simon Flexner, New York City; Charles F. Stokes, Surgeon-General U. S. Army, and Harvey Cushing, Baltimore, who is to be in charge of the surgical side of the new Peter Bent Brigham Hospital, now in process of construction.

Medical Library Meetings.—The Medical Library Meetings, which are under the joint supervision of the officers of the Suffolk District Medical Society, those of the Medical Section and those of the Surgical Section of the same society, and of a committee of the Boston Medical Library, were resumed October 28. The subject for discussion at the first meeting is "The Recent Epidemic of Septic Sore-Throat." It will be discussed by Prof. C. E. A. Winslow, of New York; Drs. Mark W. Richardson, Samuel H. Durgin, Joseph L. Goodale and Richard M. Smith, Boston; Dr. Eugene A. Darling, Cambridge, and Dr. H. Lincoln Chase, Brookline. Hereafter these meetings will be held on the first and third Wednesday evenings of each month, beginning November 15. The topic for that date is "Pathology and Medical Treatment of Exophthalmic Goiter," by Dr. Charles F. Hoover of Cleveland, O., with discussion by Dr. Charles H. Mayo and others.

MICHIGAN

Maternity Hospital Licensed.—The board of health of Grand Rapids has voted to grant a license to the United Brothers Association Hospital, to operate a maternity hospital in conformity with the new state law.

Antituberculosis Society Issues Circular.—The *Hastings* Antituberculosis Society has issued an attractive circular giving valuable *information concerning the* care of persons suffering from tuberculosis, the means of *preventing* the spread of the disease and its cure.

New Wing of Hospital Open.—The new wing of Grace Hospital, Detroit, was open for inspection, October 2. The new building is fireproof and is equipped with most modern appliances. Dr. Harold Wilson has established a private surgical clinic at the hospital, for the operative treatment of diseases of the eye, ear, nose and throat.

Additional Medical Officers Commissioned.—The state military board is taking action to reorganize the medical department of the National Guard to conform to the federal regulations. The board recommended the following officers for commissions as first lieutenants in the medical corps: Howard A. Grube, Grand Rapids; George H. Townsend, Jackson; Floyd A. Roberts, Flint; Alfred E. Lemon, Sault Ste. Marie, and Lewis S. Ramsdell, Manistee.

Whooping-Cough Dangerous to Children.—Calhoun County Medical Society, at its recent meeting at Marshall, adopted resolutions setting forth that pertussis is one of the most fatal of the contagious diseases of childhood, and expressing the desire that through the efforts of the board of health and health officers, the public may be better instructed as to the dangers of this disease, that it may be reported, and that stringent quarantine regulations may be enforced.

Personal.—A banquet was given by the Manistee County Medical Society, October 6, in honor of Dr. Jens A. Christensen, who was about to leave Manistee to practice in Chicago.——Dr. William A. Spitzley, Detroit, has returned from Europe.——Dr. John E. Clark, Detroit, chemist of Wayne County, was thrown from his motor car in a collision with another automobile, and sustained a severe scalp wound.——Dr. and Mrs. Harry A. Haze, Lansing, have returned from Europe.——Dr. Zell L. Baldwin, Niles, has taken charge of the antituberculosis hospital at Kalamazoo.

NEBRASKA

Personal.—Dr. Susan La Flesche-Picotte, Walthill, is *reported to be seriously ill as* the result of overwork.——Dr. James W. Miller has been appointed surgeon of the Union Pacific system at Gibbon.——Dr. Albon E. Bartoo has disposed of his interests in Arcadia and will move to Brazil, South America.——Dr. John B. Fulton, Beatrice, sustained serious injuries in a fall down a stairway at his home, October 5.——Dr. Anders P. Overgaard, Fremont, was seriously injured by a fall on a cement floor, October 4.——Dr. Henry G. Leisenring, Wayne, has sold his practice and will move to San Diego, Cal.——Dr. Gustav W. Dishong, assistant superintendent of the Norfolk Insane Hospital, has been appointed superintendent of the Lincoln Insane Hospital, vice Dr. John T. Hay, *deceased.*

NEW JERSEY

Personal.—Dr. William Edgar Darnall, Atlantic City, has been appointed consulting surgeon to the North American Children's Sanitarium for the Treatment of Surgical Tuberculosis, Atlantic City.

Society Meeting.—The New Jersey State Pediatric Society at its meeting, October 28, held in Lakewood, N. J., held a symposium on "The Welfare of Young Children from the Educational Standpoint," at which Henry E. Jenkins, New York City, district superintendent of schools, discussed "The School and the Doctor;" Prof. Howard C. Warren, Princeton University, "The Home Schools for Infants at Rome;" E. R. Johnstone, superintendent of the New Jersey Training School for Feeble-Minded Girls and Boys, Vineland, "The Care and Training of Feeble-Minded Children;" and Dr. David F. Weeks, superintendent New Jersey State Village for Epileptics, Skillman, "What New Jersey is Doing for the Epileptic."

NEW YORK

Personal.—Dr. Alonzo B. Foster, Fonda, has been *appointed* coroner of Montgomery County, vice Dr. Cornelius W. De Baun, deceased.——Dr. William Charles Willis, *Patchogue*, is said to have been committed to the State Hospital for the Insane, Central Islip, October 15.

To Warn Children Against Accidents.—The trolley men of the state are perfecting plans to educate children as to the danger of accidents. With the cooperation of teachers and parents, personal talk, pamphlets of warning information and danger signs calculated to impress boys and girls are to be presented in school room, home and playground throughout the state. On blotters and other attractive souvenirs have been printed such maxims as "Don't hitch to a car, touch loose wires, play on tracks, jump off until the car stops, cross tracks till you look, or send your little brother or sister alone." Recent reports of the public service commission show that accident damages have cost the street railways of the state almost $5,000,000 in one year. Superintendent Maxwell of New York City has sent circulars to the public schools requesting that instructions be given the pupils in regard to the serious evil of jumping on the tail end of street cars, wagons and other vehicles. The principals were also asked to instruct children how to get on and off street cars safely and how to cross the street where vehicular traffic is heavy. In twenty-one months there have been 239 children killed in street accidents in *Greater New York.*

District Society Meetings.—At the fifth annual meeting of the First District Branch of the Medical Society of the State of New York, held in Yonkers, October 12, Dr. Daniel Bailey

Hardenbergh, Middletown, was elected president; Dr. John Calhoun Otis, Poughkeepsie, vice-president; Dr. Charles Ellery Denison, New York City, secretary, and Dr. George Swan Mooney, Yonkers, treasurer.——The Fifth District Branch of the Medical Society of the State of New York held its annual meeting in Utica, October 5, and elected the following officers: president, Dr. James K. Stockwell, Oswego; vice-president, Dr. Amos P. Dodge, Oneida; secretary, Dr. Frederick Flaherty, Syracuse, and treasurer, Dr. Henry A. Hoyt, Watertown.——The annual meeting of the Sixth District Branch of the Medical Society of the State of New York was held in Elmira, October 17. Dr. Frederick M. Miller, Binghamton, was elected president; Dr. Herbert W. Fudge, Elmira, vice-president, and Dr. Luzerne Coville, Ithaca, secretary and treasurer. It was decided to hold the 1912 meeting in Binghamton.——The fifth annual meeting of the Fourth District Branch of the Medical Society of the State of New York was held in Ogdensburg. Dr. Frederick G. Fielding, Glens Falls, was elected president; Dr. Silas J. Banker, Fort Edwards, vice-president; Dr. Frederick K. Resseguie, Saratoga Springs, secretary, and Dr. George H. Oliver, Malone, treasurer. Glens Falls was selected as the next place of meeting.

New York City

Harvey Lecture.—Professor Max Verworn, University of Bonn, delivers the third of the present course of lectures at the New York Academy of Medicine on Saturday evening, October 28, at 8:30, on "Narcosis."

Inoculate Militiamen Against Typhoid.—Preparations are being made to inoculate every man in the Seventy-First Infantry, N. G., N. Y., in order to prevent typhoid fever at the encampment next summer. This is the first volunteer regiment to submit to inoculation against typhoid fever.

Personal.—Dr. Stephen Smith has been elected president of the New York State Conference of Charities and Corrections.——Dr. William L. Gahagan, medical director of the United States Casualty Company, has resigned to accept the superintendency of the personal accident and health insurance department of the Globe Indemnity Company.

Deaths of the Quarter.—During the three months ended September 30 there were 18,048 deaths reported, equivalent to a death-rate of 14.38 per 1,000, a decrease of 1.15 as compared with the corresponding quarter of last year. The chief decrease was shown in diarrheal diseases of children under 5 years of age, nephritis, pneumonia, congenital debility and tuberculosis of the lungs.

Hospital Addition Opened.—The annual meeting of the Society of St. Luke's Hospital on October 18 was preceded by the formal opening of the Travers Pavilion, the erection of which was made possible by the will of Mrs. Mary Travers Heckscher which gave $250,000 for this purpose. This addition is a ten-story building, the two upper stories of which have arrangements for open-air treatment of patients.

Anesthetists Meet.—The meeting of the anesthetists of New York City and vicinity, held at 40 East Forty-First Street, Manhattan, October 28, consisted of a dinner at 6 p. m., a business session of the Long Island Society of Anesthetists for reorganization, addresses on "The Anesthetic Situation in New York," by Dr. Alfred M. Hellman and on "Personal Reminiscences and Experiences of Ten Years of Anesthetic Work," by Dr. Freeman Allen, of the Massachusetts General Hospital, at the conclusion of which the society adjourned to attend the Harvey Society lecture on "Narcosis."

Call to Fight Rabies.—The large number of persons bitten by dogs and the increase in frequency of rabies has called forth a bulletin from the department of health setting forth the urgent need of taking measures to combat present conditions. According to figures compiled by the department of health, 2,462 persons were bitten by dogs in this city from January 1 to September 1 this year, and of these, 1,743 were children. Examination of the animals killed showed six rabid cats and 192 rabid dogs. The net result was seven fatal cases of human rabies. The department of health calls for the immediate passage and the rigid enforcement of an ordinance requiring that dogs at large be either muzzled or leashed. The department also advises a campaign of educational measures in regard to the care and observation of dogs by their owners. It is thought that an adequate system of licensing by the municipal authorities might have a beneficial effect and the city of New York seems to be about the only city in which the licensing of dogs is not a function of the municipal government.

NORTH CAROLINA

Personal.—Dr. and Mrs. Charles L. Summers, Winston-Salem, will sail for Europe early next month.——Dr. Baxter S. Moore, Charlotte, will remove to Atlanta, Ga., November 1.

New Infirmary.—The executive board of the trustees of the State Hospital for Tuberculosis, Montrose, at its recent meeting in High Point, awarded the contract for the erection of a new infirmary to afford accommodation for fifty additional patients.

Courses in Sanitation at Trinity.—Trinity College, Durham, with the cooperation of its department of biology and the faculty committee on health, has arranged demonstrations and courses of instruction for its students, in the fundamentals of sanitary science, which for several years physicians urged should be an essential part of a complete modern college course.

PENNSYLVANIA

Examination of Public School Children.—Medical examination of the Lebanon public school children has been decided on, to assist in stamping out diphtheria.

Personal.—Dr. D. Walter Straub, Bethlehem, is reported to be seriously ill with septicemia.——Drs. Thomas A. Monahan, Shenandoah, and John L. Adams, Asheville, N. C., have been appointed assistant surgeons at Fountain Springs Hospital.

Conference of Secretaries.—The conference of the secretaries of the component county societies of the Medical Society of the State of Pennsylvania was held in Harrisburg, September 26, Dr. John J. Coffman, Scotland, presiding. After the completion of the literary program the members were entertained at a dinner given by the state medical society, at which Dr. Thomas S. Blair, Harrisburg, was toastmaster. Dr. Luther B. Kline, Catawissa, was elected chairman and Dr. Clarence E. Shaw, Williamsport, was reelected secretary-treasurer.

Pavilion for Sick Children.—On October 22, a pavilion for the treatment of indigent consumptive children was dedicated at the Philadelphia Jewish Sanitarium, Eagleville, Montgomery County, an institution devoted exclusively to the free treatment of tuberculosis. The pavilion has accommodations for sixteen children as well as facilities for their education. Only children in the incipient stages of the disease will be accepted. This institution was started more than two years ago and has discharged 130 patients as cured. It now has seventy-five patients and a waiting list of nearly 150.

Philadelphia

Club Reception to Clinicians.—The next reception of the Medical Club of Philadelphia will be held November 17, at which Dr. Albert J. Ochsner, Chicago, the president of the Congress of Surgeons of North America, and the president-elect will be the guests of honor.

Election in New Society.—The Philadelphia Laryngological Society, recently organized and whose first meeting was held October 25, has chosen the following officers: president, Dr. Ross H. Skillern; vice-president, Dr. George W. Mackenzie, and secretary and treasurer, Dr. Charles A. O'Reily.

Personal.—Dr. Alexander W. Biddle is recovering from the effects of a slight operation performed at the Pennsylvania Hospital.——Dr. Louis Starr sailed October 18 to spend the winter in Europe.——Dr. Charles Lincoln Furbush has returned from Europe.——Dr. Louis O. Heiland has been appointed secretary to the board of directors of Girard College.

Municipal Dental Laboratory.—Bids have been opened by the director of public health and charities for the equipment of a dental laboratory in city hall; drugs, medicines, surgical instruments and supplies and for the purchase and installation of a modern *x*-ray apparatus. The department has $1,700 for dental supplies; it has $5,922.75 for a new *x*-ray machine at Blockley and has $120 for drugs.

War on Fake Doctors.—War on fake doctors who are swarming here from "physical culture" schools in other cities is to be opened by the Philadelphia County Medical Society. At the meeting of the society October 16, a resolution was passed, providing for action at the second meeting in November toward joining forces with the district attorney in the campaign to compel the so-called "mechanotherapists" and others to discontinue the practice of medicine. These questionable commercial characters, pretending at first to give treatments only under physicians' orders, soon blossom out as doctors, thus evading the statutes on the practice of medicine.

GENERAL AND FOREIGN

Railway Surgeons Hold Meeting.—At the annual meeting of the American Association of Railway Surgeons, held in Chicago October 18-20, the following officers were elected: president, Dr. Rhett Goode, Mobile, Ala.; vice-presidents, Drs. Arthur M. Hume, Owosso, Mich.; Robert A. Kerr, Peoria, Ill.: and Henry H. Clark, McGregor, Ia.; secretary-editor, Dr. Louis J. Mitchell, Chicago (reelected), and treasurer, Dr. Henry B. Jennings, Council Bluffs, Ia.

Meeting of Soo Line Surgeons.—The Minneapolis, St. Paul and Sault Ste. Marie Railway Surgical Association held its fifth annual meeting in Chicago October 16-17, under the presidency of Dr. Albert E. Halstead, Chicago, Ill. The following officers were elected: president, Dr. Charles A. Stewart, Duluth, Minn.; vice-president, Dr. H. Jefferson O'Brien, Superior, Wis.; and secretary-treasurer, Dr. John H. Rishmiller, Minneapolis, Minn. (reelected). The next annual meeting will be held in August, 1912, in Duluth.

Honorary Degrees Conferred on Physicians.—At exercises attending the five-hundredth anniversary of the foundation of the University of St. Andrews, Scotland, the honorary degree of LL.D. was conferred on eighty-six eminent men, of whom the following were members of the medical profession: Sir Thomas Clifford Allbutt, regius professor of physic in the University of Cambridge; Sir Thomas Barlow, professor of clinical medicine, University College, London; George Andreas Berry, president of the Royal College of Surgeons, Edinburgh, and of the Ophthalmological Society of the United Kingdom: Byrom Bramwell, president of the Royal College of Physicians, Edinburgh; Robert Bridges, physician, critic and poet; Alexander Crum Brown, formerly president of the Chemical Society, chemist and physiologist; Sir Hector Clare Cameron, formerly president of the Faculty of Physicians and Surgeons, Glasgow; Francis Gotch, Waynflete professor of physiology in the University of Oxford; Peter Fredrik Holst, Christiania, president of the Norwegian Institute for Medical Science; William Williams Keen, Philadelphia, president of the American Philosophical Society; Hector Leboucq, professor of anatomy, and dean of the Faculty of Medicine in the University of Ghent; Charles Sedgwick Minot, Boston, professor of histology and embryology in Harvard Medical School and secretary of the Elizabeth Thompson Original Research Fund; Rutger Adolf Reedingius, rector and professor of pathologic anatomy in the University of Groningen; Robert Saundby, president of the British Medical Association and professor of medicine in the University of Birmingham; Edward Albert Schäfer, professor of physiology in the University of Edinburgh and president-elect of the British Association, and Johannes Veit, professor of obstetrics and gynecology, and rector of the University of Halle-Wittenberg.

LONDON LETTER

(From Our Regular Correspondent)

London, Oct. 14, 1911.

Death of John Hughlings Jackson

John Hughlings Jackson, M.D., F.R.C.P., LL.D., D.Sc., F.R.S., consulting physician to the London Hospital and the National Hospital for the Paralyzed and Epileptic, died at his residence in London at the age of 76. Born in Yorkshire, he studied medicine at St. Bartholomew's Hospital, London, and graduated at the Scotch University of St. Andrews. In 1859, largely through the introduction of Sir Jonathan Hutchinson, another Yorkshireman, who was also a schoolfellow, he was appointed lecturer on pathology at the London Hospital. He entertained the idea of pursuing a literary career and giving up medicine but was persuaded not to do so by Sir Jonathan Hutchinson, who afterward described Jackson as his "greatest discovery." In 1864 he was appointed assistant physician to the London Hospital and lecturer on physiology. In company with J. S. Ramskill and C. B. Radcliffe he founded the National Hospital for the Paralyzed and Epileptic, the home of the English school of neurology, of which he has been well described as the father. His contributions to neurology were both numerous and important. An incomplete index to his publications from 1861 to 1894 reached the extraordinary total of 202. His work on aphasia and convulsions and his description of the form of the latter to which his name has been given may be particularly mentioned, but there was scarcely a problem in the whole field of neurology that was not illuminated by his genius. With the other eminent neurologists he may be described as a great clinician, but he differed from them all in one respect: he united the speculations of the philosopher to the facts observed at the bedside. A pupil of Herbert Spencer, he applied this philosopher's doctrines of evolution to neurology. He showed how brain disease conformed to the law of "dissolution" formulated by Spencer. Reasoning in this deductive fashion he postulated the existence of three levels of nerve-centers according to their position in evolution. He showed how the phenomena of brain disease conformed to the law of dissolution in affecting first the highest centers, then the middle centers and finally the lowest. By thus combining philosophical speculation with clinical observation he achieved unparalleled success and anticipated many of the discoveries of the experimental methods. Thus in his "Study of Convulsions" he postulated the existence of a motor area in the cortex, of centers in that area, and their arrangement—a speculation subsequently confirmed by the experiments of Fritsch, Hitzig and Ferrier.

The Royal Commission on Tuberculosis

The final report of the Royal Commission on Tuberculosis has been reviewed in a previous letter (The Journal, Aug. 5, 1911, p. 491). The first two of the extensive appendixes have just been published containing complete details of the experiments and observations and calling for some further notice. They are very valuable because of the minute accuracy and detail with which a long series of experiments has been described. To determine the character of the bacilli active in the production of tuberculosis in man, cultures from fifty-four cases representative of all the common types, except lupus, were used. In the cases of generalized tuberculosis caused by bacilli admitted through the alimentary tract, cultures were isolated, not only from the glands nearest the point of entry, but also from distant lesions. In two cases, human and bovine bacilli were isolated from the same patient, but in the other cases, the bacilli were either distinctly bovine, growing with difficulty in artificial media and of high virulence, or human, growing luxuriantly and of low virulence for the rabbit, but of much lower virulence for the calf than the bovine type. Bovine bacilli were isolated from four out of ten cases of alimentary tuberculosis in children and from two cases of pulmonary tuberculosis. Four children died as a result of infection with bovine tubercle bacilli, the cause of death in one case being general tuberculosis; in the second, tuberculous meningitis; in the third, tuberculous peritonitis, and in the fourth, stricture of the intestines following tuberculous ulceration. The two pulmonary cases occurred in adults, aged 21 and 31 years, respectively.

The question of a possible modification of the bacilli from the human to the bovine type or vice versa as a consequence of residence in the human or animal body was discussed. The bovine type in man was obtained almost solely from children, in whom it had presumably entered through the alimentary canal. The disease produced varied in severity. In the majority of cases it was fatal; in the remainder, it was apparently limited to the cervical glands or was found in children who had died from other causes. Considering the many opportunities which the bovine bacillus has for entering the human body there must be many children who survive the invasion. What then is the fate of the invaders? As bovine bacilli are rarely found in the tuberculosis of adults, they must either be eventually killed or changed into bacilli of the human type. To prove the latter is very difficult. The problem has been attacked by the investigation of many different strains of tubercle bacilli from human lesions with a view to ascertaining whether there exist types intermediate between the human and the bovine, and also by the passage of various strains of tubercle bacilli through different species of animals to determine whether the properties (with regard to culture and virulence) are stable or capable of being altered. The general result of these experiments lends no support to the view that human bacilli can be changed into bovine bacilli by passage through calves or other mammals.

In a case of lupus a culture was isolated which differed from all other human bacilli grown from human tuberculosis. It possessed the cultural characters of a bovine bacillus but had a relatively low virulence for the calf. This led to an investigation to determine whether the bacilli of lupus were different from the bacilli of other forms of human tuberculosis. The general result was that cultures from lupus fall into one or other of the two main divisions of bacilli (human and bovine) as far as their cultural characters are concerned. But few possess the degree of virulence which these characters would indicate. It was thought that some of the cultures might be bovine bacilli which had become attenuated in virulence either before their entry into the human body or as a result of residence therein. Exhaustive experiments, however, showed that the lupus type cannot be regarded as intermediate between the bovine and human types but seems to be a degenerate form of the human type.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Oct. 6, 1911.

The Death of M. Troost and the Candidacy of Mme. Curie for the Academy of Science

M. Louis-Joseph Troost, member of the Académie des sciences since 1884, at which time he succeeded Wurtz, has just died, aged 85, and in consequence the question of the entry of women to the institute has been raised again. Many members of the academy are wondering if Mme. Curie would once more become a candidate. It is certain that she would now have the greatest chance of being admitted. The principal argument against her last year was the high merit of M. Branly, who is now a member of the institute. Mme. Curie would, therefore, probably have a majority of votes. It is inevitable that there would be some opposition, since many members of the academy have an intense horror of feminism, but these devotees of tradition would not be able to sway the final results.

The Consumption of Brandy

Dr. Jacques Bertillon, *chef des travaux de la statistique municipale de la ville de Paris*, has just presented to the Académie des sciences morales et politiques, an analysis showing the consumption of brandy in thirty-three large French cities. It appears that in all the consumption of brandy has diminished considerably since 1900-1901, that is to say, since the law of Dec. 29, 1897, reducing the tax on wine and beer and increasing considerably the taxes on distilled liquors. Formerly the consumption of brandy was almost the same in all the groups of cities, that is to say, from 7 to 8 liters of alcohol per year per inhabitant. It was only 2.84 liters in the country. Since 1901 it has fallen to 6 liters in small cities of 4,000 to 10,000 inhabitants, to less than that in the cities a little larger, and to a still smaller figure (4.23 liters) in the cities of more than 50,000 inhabitants. The diminution has been great, therefore, in the large cities; there has been no decrease in the country. The consumption of wine, meanwhile, has increased.

Scarcity of Milk in Paris

For some time Paris has been suffering from a scarcity of milk, which tends to become chronic, since the demand for milk in Paris amounts to 1,100,000 quarts per day, and no more than 900,000 quarts are received. It is in vain that the large milk companies have trebled the extent of territory from which they draw milk, and to-day go as far as 180 miles (300 kilometers) to obtain what they formerly obtained at 60 miles at the maximum. This insufficiency of production is due to three principal causes: the drought which has dried up the pastures; foot-and-mouth disease, which has decreased the herds, and the higher prices and smaller numbers of the dairy employees. Although the situation is not alarming for the hospitals, milk being furnished for the Public Charities by contract, it is rather disturbing for the general population. The prefect of police has accordingly interviewed the presidents of the dairy companies. Measures have been taken so that infants, sick persons and the aged shall not feel the effect of price. In all the dairies a notice has been posted requesting persons having young children or sick persons or old persons in the family to indicate the quantity of milk which is necessary for them in order that it may be reserved each day.

Measures Against Depopulation

The commission on depopulation has just terminated its labor by the adoption of the general report of its president, M. Paul Strauss, senator. Crimes against infants, more particularly infanticide, have, in our day, taken the most hypocritical and refined form, being encouraged by a doctrinal and practical propaganda. Judicial repression is altogether insufficient. Thus in 1906, out of 736 cases of concealed childbirth, 713 infants were abandoned. The commission adopted the resolution of the Ligue de la mortalité infantile, calling for a strict oversight of midwives and lying-in homes and a rigid repression of the neomalthusian propaganda by lectures, tracts, etc. They recommended, on the other hand, the encouragement of maternity by all possible means before and after birth. It is necessary to avoid overwork which exercises a bad effect on the woman and to combat the ignorance which has a large share of the responsibility for preventable accidents. The secret lying-in homes shelter future mothers who wish to hide their fault at any cost and also the *déracinées* and vagabonds. Some form of charity or mutual assistance is necessary to protect the future mother. Stations of observation are indispensable in our popular centers to insure physiologic preparation for maternity. After the accouchement a respite from work of at least four weeks is imperiously demanded. The bill now before the senate, after having been unanimously passed by the Chamber of Deputies, ought to be passed without delay. During the period of accouchement and afterward, the combat against ignorance demands especial vigilance. The infant consultation is the instrument best adapted for educating mothers and keeping the medical control of infants.

After having examined the question of children aided in various ways, M. Paul Strauss has studied the sanitary protection of children aged 1 to 14 years, and of adults. For the former he especially recommends the institution of the sanitary school record (*casier sanitaire scólaire*), such as is used in Geneva, with continued oversight and intelligent education from the point of view of hygiene and preventive medicine. School lunches, vacation colonies, stations for convalescents, should be used in the struggle against transmissible diseases, tuberculosis and degeneration.

M. Strauss showed that according to the tables drawn up for the period extending from 1898 to 1903 by M. Lucien March, head of the general statistics of France, out of 1,000 new-born infants the following number survived to one year in the countries named respectively:

France	8.435
England	8.691
Denmark	8.799
Belgium	8.880
Sweden	9.079

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Oct. 5, 1911.

Personals

September 28, Professor v. Michel, director of the Berlin University eye clinic, died at the age of 68. When some lay and medical journals about two months ago published the news that he intended to resign his position at the end of the winter semester, he contradicted it with the statement that he had not thought of leaving his service. Now, however, death has contradicted his assertion. Michel died from contracting kidney and tuberculosis. He was an excellent investigator and teacher, who had enriched his specialty with a number of works. His text-book also received a considerable circulation through several editions.

As a result of the removal of Professor Killian to Berlin, privat-docent Dr. Marx has provisionally undertaken the direction of the Freiburg laryngologic clinic.

Closing of Bilz's Quack Hospital

The renowned quack Bilz who by his vast advertising has circulated by the hundred thousands a "Nature Cure Book" (*Naturheilbuch*) published under his name, but surely prepared by some one else, has been deprived by the authorities of the concession for the maintenance of his institution located at Niederlösnitz near Dresden, on account of the objections raised on hygienic and moral grounds against the conditions existing there.

The Meeting of the German Society for the Advancement of Science

The annual *Naturforscher* congress was held this year at Carlsruhe, as usual in the latter part of September. The attendance was not so large as at previous meetings, in spite of the fact that the program of addresses and entertainments was very inviting. In the medical section a number of important subjects were treated. The pathology and therapy of exophthalmic goiter was discussed by Professor Gottlieb of Heidelberg from the pharmacologic standpoint, by Professor Simmonds, as a pathologic anatomist, by Professor Starck of Carlsruhe, as an internist from the clinical standpoint, diagnosis and therapy, and by Professor Rehn of Frankfurt a. M., with reference to the operative results. The Freiburg professors Aschoff, Krönig, de la Camp and Professor v. Beck, the surgeon of Carlsruhe, delivered addresses on thrombosis and embolism. Professor Biedl of Vienna, and Professor Morawitz of Freiburg reviewed the subject of internal secretions.

EHRLICH ON SALVARSAN

Great interest was naturally aroused by the address of Ehrlich on salvarsan, which I would like to report to your readers in detail. Ehrlich first addressed himself to a criticism of the publications regarding the injurious effects of salvarsan. He said that it was easy to show that certain injurious effects which were at first laid to salvarsan, were in fact due to other agencies. Thus the bladder disturbances depended on the use of a product that had become poisonous on account of oxidation. The same was true of other accidents. In regard to the numerous side-effects which had appeared, such as fever, headache, vomiting and diarrhea, and which occasionally assumed a serious character, Wechselmann first pointed out that these phenomena must be connected with the bacterial content of the distilled water used for solutions and showed that these practically disappeared with the use of an absolutely fresh distilled water. This peculiar phenomenon is explained by Ehrlich by the supposition that under the influence of bacteria the body cells acquire an increased sensitiveness to arsenic. This circumstance must influence the process of sterilization unfavorably, aside from the fact that the febrile reaction, when it is severe, may exercise a fatal influence on weak individuals with disease of important organs. Further Ehrlich maintains that it is possible that under such a reaction to the endotoxins, disease processes will be favored and that even the symptoms referable to the cranial nerves are connected with this fact.

NEURORECURRENCES AFTER SALVARSAN

In no other way can be explained the fact that in certain clinics, as for instance that of Finger in Vienna, such neurorecurrences are unusually frequent. Independently of this we must consider the possibility that such a stormy reaction injures the cells so as to make them supersensitive to a second injection of salvarsan. Other by-effects which have played a great rôle are those affecting the nervous system. Among these we must distinguish two groups, those occurring within a short time after the injection and those which appear later, from two weeks to one, three, or rarely four months. The first type of quickly appearing functional nerve disturbances are explained most simply by supposing that after the destruction of the spirochetes, a swelling of the affected part sets in, such as may be observed as Herxheimer's reaction in the skin under salvarsan treatment. But in a narrow bony canal such a reaction will not run so harmless a course but will cause pressure on the nerves. More important is the group of nerve symptoms, called nervous relapses or neurorecurrences, which were originally attributed to poisoning by arsenic. Dr. Benario has compared 194 nervous relapses under salvarsan treatment with 122 cases under mercurial treatment, and he was able to establish the fact that under the latter treatment the same affections, e. g. those of the auditory nerve, occur under like conditions. From this Ehrlich concludes that the opinion that nervous relapses under mercurial treatment are rare is not correct. In certain clinics an unusual number of nervous relapses under salvarsan have occurred. On the other hand in certain localities, in especially large clinics, they are practically unknown. After a thorough discussion of the factors that indicate that in these nervous relapses we have to do with the propagation of the few spirochetes which have survived, and not with an injury to the nerves, Ehrlich continues: "The cause of the nervous relapses is to be referred to the fact that almost the entire number of syphilis germs in the body have been destroyed and only isolated spirochetes remain alive. We have to do with a sterilization that is almost complete. These few germs are placed under better life conditions because their competitors have been expelled. Since from anatomic reasons the action of salvarsan is more difficult in the nervous tissues, most of the residuary spirochetes are found here and come therefore most markedly and earliest into evidence."

FATALITIES

As regards the fatal cases in connection with salvarsan, Ehrlich remarks that we have to do with a large number of treated cases and a small number of these cases are patients in whom salvarsan was tried as a remedy of last resort. When we consider that in the course of the last year several hundred thousand patients have been treated with salvarsan, the number of accidents is so small as to give no occasion for any serious objection. It may be affirmed that salvarsan has been shown by the experiences of the last year to be a relatively harmless substance. We have seen that the acute reaction to it is due to a lack in technic.

TREATMENT BY A SINGLE LARGE DOSE

Ehrlich then discusses the principle of treatment by *sterilisatio magna*. In numerous experiments the undoubted cure of severely affected animals has thus been achieved. In Russia it has been shown by wholesale experiments in spirillosis of hens and geese, that salvarsan is able: 1. to cure a severely affected animal permanently by a single injection. 2. Salvarsan has shown itself to be a really wonderful means of sterilization in relapsing fever in Russia, Spain, and the Congo. A single injection is sufficient to free the patient at once from the parasites and lead to a permanent cure. 3. The results in frambesia are quite as brilliant. In Surinam in all 900 frambesia patients were treated and of these only three relapsed. In the frambesia hospital in Surinam 828 frambesia patients were treated within a week. Two weeks later the last patient was in a condition to be discharged from the hospital and thus in the history of medicine this was the only instance in which the hospital could be closed. 4. In tertian malaria salvarsan achieves a remarkably curative effect. 5. Bilharzia seems to be sterilized by a single injection. 6. From extensive trials an injection of 30 gm. of salvarsan effects a cure in the murrain of horses (epizootic). Also in the so-called African *Rotz* a single injection of salvarsan cures the animal. Finally oriental sore which is caused by *Leishmania* is cured by salvarsan. It seems that in suitable forms of syphilis salvarsan used in sufficiently large and frequent doses is capable of effecting a complete sterilization of the body, and that in these cases results can be obtained that are not attainable by mercury. On the other hand, it seems that by a combination of salvarsan with mercury excellent results are obtained and that by means of this combination it is possible to secure results with smaller amounts of salvarsan than without it. By many authors emphasis has been laid on the point that from the sociologic standpoint our most important task is to treat syphilis in its early stages. It seems possible in over 90 per cent. of the affected cases to secure the healing of primary syphilis.

OUTLOOK

After a thorough exposition of the most suitable methods of early treatment Ehrlich concludes: If the result of securing a final cure in the great majority of cases of primary syphilis should be achieved, a very important forward step in the attempt to abolish this fearful plague would have been taken. Whether a permanent cure is possible in the later stages and to what extent must be determined by further experience.

VIENNA LETTER

(From Our Regular Correspondent)

VIENNA, Oct. 10, 1911.

Some Grievances Against the Proposed New Medical Act

The government has quite recently worked out a new medical act to replace the old one (from 1801), and has invited the medical councils to cooperate in its working; the councils have unanimously refused to undertake such a task in the short space of time allotted for its accomplishment. Moreover, several features of the act have called forth violent remonstrances from the majority of the practitioners. Thus, for instance, it is intended to bring into force the "numerus clausus" as regards practitioners in towns with more than 50,000 inhabitants, and in the *Curorte* (health resorts). Free competition would thus be made impossible. Another article deals with the medical boycott. The act would nullify and make punishable all negotiations or contracts between physicians by which parts of the population, districts or towns should not receive medical help. This aims at the most useful weapon of our profession here, which made possible the successful issue of several medical strikes where contract practice and club practice were at stake. Already the councils are conducting an action of protest against the act as such, and there is no possibility that it will become law before a year. By that time the profession will have drawn up a "medical act" of its own, wherein the interests of the profession and those of the public will be brought into harmony as far as possible.

Moving of the Laryngologic and Pediatric Clinics

Within the last week the clinics for rhinolaryngology and for diseases of children have moved out of their old premises into their new grand houses. The new institutes provide for growth. Although at present they have each about 100 beds, the number can be increased by 50 per cent., if required. They are fitted most lavishly and absolutely up to date, according to the requirements of the professors (Chiari and von Pirquet). A more detailed description will be forthcoming in due time. A point worth mentioning is that in future the assistants of the clinics will not be allowed to follow up private practice in the hospital, as was hitherto the custom. The space occupied hitherto in the old house by these two clinics will be speedily converted, partly into laboratories and partly into use for new buildings.

Marriages

Harriet M. Wiley, M.D., and Edward W. Whitney, M.D., both of Northampton, Mass, at Tenants Harbor, Maine, October 12.

Clarence Adair Rhodes, M.D., Atlanta, Ga., to Miss Agnes Stewart Plummer, at Washington Grove, Md., October 12.

Richmond Favour, M.D., Boston, Mass., to Miss Dorothy Georgia M. Chapman of Bowdoinham, Maine, October 11.

Malcolm Cameron Rose, M.D., New York City, to Miss Mary Ella Dunning of West Orange, N. J., October 10.

Emory D. Bernard, M.D., to Miss Nina deWolfe, both of Port Arthur, Texas, at Beaumont, Texas, October 11.

David Barton Penniman, M.D., Argyle, Ill., to Miss Fannie Littell Rudgers of Montclair, N. J., October 4.

Walter D. Chase, M.D., Bethlehem, Pa., to Miss Helen M. Harleman of South Bethlehem, Pa., October 7.

Whedon W. Mercer, M.D., Washington, Ill., to Miss Kathryn J. Giblin of Kankakee, Ill., September 20.

Roy Hamilton Peck, M.D., Springfield, Mass., to Miss Alice Jemima Campbell, at Baltimore, October 11.

Oscar Milton Marchman, M.D., Dallas Texas, to Miss Martha Jenkins of Waco, Texas, October 26.

William Plumer, M.D., Farmington, Ill., to Miss Pearl C. Winters of Pittsburgh, Pa., September 25.

Jesse R. Kauffman, M.D., Blue Island, Ill., to Miss Alice Jane Roudthaler of Chicago, October 12.

Frederick G. Sigman, M.D., Spencer, N. C., to Miss Louise Wilson of Durham, N. C., October 8.

John W. Stevenson, M.D., Palouse, Wash., to Miss Blanche Campbell of Omaha, Neb., recently.

Elmer Le Roy Biggs, M.D., Los Angeles, Cal., to Miss Grace Wentworth of Chicago, October 12.

George T. Penn, M.D., to Mrs. Gertrude M. Hughes, both of Spokane, Wash., October 4.

Thomas J. Talbott, M.D., Baltimore, to Mrs. Mary J. Carland, at Baltimore, October 9.

J. Frank Small, M.D., York, Pa., to Miss Anna M. Howell of Harrisburg, Pa., October 4.

Louis C. Swartzlander, M.D., to Miss Mona Dillon, both of Omaha, Neb., October 25.

Juniattus A. Fisher, M.D., to Miss Emily L. Smythe, both of St. Louis, October 12.

Martin Kutscher, M.D., to Miss Helene Kahn, both of New York City, October 5.

Walter H. Pilger, M.D., to Miss Bertha Wilkins, both of Norfolk, Neb.

Deaths

Alexander Hugh Ferguson, M.D., a prominent surgeon of Chicago, died at his home in that city, October 20, from diabetes, aged 58. He was born in Ontario, and was an honor graduate of the Medical College of the Trinity University in 1881. He began practice in Manitoba in 1882, where he remained until 1894, when he moved to Chicago. He was one of the founders of Manitoba Medical College, Winnipeg; for three years was professor of physiology and histology in the institution, and for eight years thereafter professor of surgery. In 1894 he was made professor of surgery in the Chicago Post-Graduate Medical School and Hospital, and since 1900 had been professor of clinical surgery in the College of Physicians and Surgeons.

His society membership included the American Medical Association, British Medical Association (in which he served as first president of the Manitoba Branch); Chicago Medical Society (of which he was president in 1910), Western Surgical and Gynecological Society (of which he was once president), the American Surgical Association and other learned societies. In 1906 Dr. Ferguson was honored by the king of Portugal with the decoration of Commander of the Order of Christ of Portugal. His hospital appointments included those of surgeon to the Winnipeg Hospital, surgeon-in-chief to St. Boniface Hospital and chief operator at Brandon and Morden hospitals, Manitoba, and after his removal to Chicago he became surgeon to the Post-Graduate Hospital and Cook County Hospital for the Insane, and was also surgeon-in-chief to the Chicago Hospital.

Dr. Ferguson had been afflicted for many years with diabetes; recently a carbuncle on the neck developed; other carbuncles formed and a condition of general sepsis followed which, with the previously existing diabetes, produced a condition too formidable for even his great strength to resist, and he succumbed at a comparatively early age and in the full tide of his professional usefulness.

Helene Knabe, M.D., formerly state bacteriologist of Indiana, was found dead in her apartments in Indianapolis, October 24, with her throat cut. She came from Germany to this country as a young girl, and paid the expenses of her medical education by her own efforts; she graduated with honors in 1904 from the Medical College of Indiana. Immediately after her graduation, she was made supervisor of the laboratories and assistant in pathology in her alma mater, and later was appointed demonstrator of pathology in the medical department of Purdue University. In October, 1905, she was appointed assistant pathologist and bacteriologist in the Indiana State Laboratory of Hygiene and later was made state bacteriologist. She resigned from this position a short time ago to devote her time to the study of hygiene and physical culture. She was a member of the American Medical Association and the Mississippi Valley Medical Association. Dr. Knabe's untimely death at the age of 35 deprives the medical profession of an enthusiastic worker in the field of hygiene and sanitation; one whose excellent qualities endeared her to her many friends.

George W. Hogeboom, M.D. Berkshire Medical College, Pittsfield, Mass., 1864; one of the oldest practitioners of Kansas; surgeon of the Eleventh Kansas Volunteer Infantry with the rank of major during the Civil War; for several terms a member of the house of representatives and senate from Jefferson County; chief surgeon of the Santa Fe System for fifteen years and organizer of the hospital system of that road; died at his home in Topeka, October 8, from pleurisy, aged 79.

William I. Bertram, M.D. University of Berlin, Germany, 1849; said to have been the oldest practitioner of Keokuk, Iowa; assistant city physician of New Orleans in 1853 during the yellow fever epidemic; from 1862 to 1864 surgeon of volunteers with the rank of major; consul to Montevideo, Uruguay in 1872 and also consulting surgeon to the Marine Hospital at that place; died at his home in Keokuk, October 3, from senile debility, aged 85.

Alsephus T. Robertson, M.D. Jefferson Medical College, 1861; formerly a school teacher in the Choctaw Nation, but since 1864 a resident of Ashmore, Ill.; for ten years town clerk and also police magistrate, supervisor and a member of the local board of U. S. pension examiners; died at the home of his son in Denver, September, from chronic gastritis, aged 77.

Philip F. Casey, M.D. University of Buffalo, N. Y., 1882; a member of the American Medical Association; for several years physician at the California State Penitentiary, San Quentin, thereafter a practitioner in San Francisco, and since the earthquake and fire, a resident of Oakland; died at his home October 1, from heart disease, aged 57.

Elisha Eugene Gilmore, M.D. Transylvania University, Lexington, Ky., 1857; Kansas City (Mo.) Medical College, 1878; formerly a member of the American Medical Association and president of the Hodgens Medical Association; died at the home of his sons in Kansas City, May 19, from pneumonia complicating mitral insufficiency, aged 75.

Annie Rose Baker-Hainer, M.D. Woman's Medical College of Pennsylvania, Philadelphia, 1903; a member of the South Dakota Medical Association and Secretary of the Public Health Education Committee of the American Medical Association for South Dakota; died at her home in Sioux Falls, June 23, from pneumonia, aged 40.

Charles Henry Hartline, M.D. Jefferson Medical College, 1892; of Oley, Pa.; local registrar of the State Board of Health; was found dead in the woods near his home October 5, as the result of shock and hemorrhage from incised wounds of the neck and wrists believed to have been self-inflicted with suicidal intent, aged 52.

William H. H. Hagey, M.D. Rush Medical College, 1868; a member of the Nebraska State Medical Association and president of the Elkhorn Valley Medical Society of Norfolk, Neb.; secretary of the local U. S. pension examining board; died suddenly in Norfolk, October 8, from cerebral hemorrhage, aged 69.

Lester W. Shean, M.D. St. Louis College of Physicians and Surgeons, 1887; for thirty-two years a practitioner of Canaan, Maine; president of the Canaan Board of Trade, selectman and a member of the school board; died at his home October 3, from heart disease, aged 65.

Frank Byron Flanders, M.D. Harvard Medical School, 1878; a member of the Massachusetts Medical Society and for several years secretary of the Lawrence Medical Club; visiting surgeon to the Lawrence General Hospital; died at his home, September 29, aged 61.

James Watson Scott, M.D. Medical College of Indiana, Indianapolis, 1879; for twelve years an assistant surgeon at the National Military Home at Danville and its branch at Marion; died at the Danville institution, October 2, from acute gastritis, aged 54.

George P. Bailey, M.D. Dartmouth Medical School, Hanover, N. H., 1882; for three years a member of the common council of Natick, Mass., and during the last year president of the council; died at his home in Natick, October 1, from nephritis, aged 53.

James Welch Guthrie, M.D. University of Michigan, Ann Arbor, 1862; of Bedford; assistant surgeon of the Twentieth Ohio Volunteer Infantry during the Civil War; died at the home of his son in Orange City, Ia., September 27, aged 84.

Frelinghuysen H. Gulledge, M.D. New Orleans (La.) School of Medicine, 1869; local surgeon of the Illinois Central Railroad at Goodman, Miss.; died at his home in that place, June 12, from chronic interstitial nephritis, aged 65.

Joseph Oliver Andrews (license, years of practice, Indiana), for nearly fifty years a practitioner of Westland, Hancock County, died at the home of his daughter in Greenfield, Ind., July 8, from cerebral hemorrhage, aged 79.

Garland J. Watkins, M.D. University of Arkansas, Little Rock, 1897; a member of the Arkansas Medical Society, and formerly president of the Boone County Medical Society; died at his home in Bellefonte, May 1, aged 35.

George Duffield Armstrong, M.D. Jefferson Medical College, 1839; one of the oldest practitioners of Chester County, Pa.; died at his home in New London, May 19, from bronchitis following whooping cough, aged 96.

Joseph M. Hollingsworth, M.D. College of Physicians and Surgeons, Baltimore, 1886; a member of the Medical Society of the State of North Carolina; died suddenly at his home in Mount Airy, April 12, aged 55.

George Washington Smith, M.D. College of Physicians and Surgeons, Chicago, 1902; died at his home in that city, October 2, from phlebitis and cardiac dilatation following pleurisy, aged 46.

Llewellyn D. Eaton, M.D. Cleveland University of Medicine and Surgery, 1871; formerly of Palatka, Fla., but for several years a practitioner of Sanford; died at his home in that city, September 18.

Newton M. Massey (license, Michigan, 1900); for more than forty years a practitioner of Newaygo; died at the home of his son in Barryton, October 4, from cerebral hemorrhage, aged 66.

William Payne Russell, M.D. Atlanta (Ga.) Medical College, 1891; of Hayneville, Ala.; died in Montgomery, Ala., April 4, from the effect of gunshot wounds of the chest and abdomen, aged 47.

Julius L. Speas, M.D. Jefferson Medical College, 1877; a Confederate veteran of Boonville, N. C.; died in church in that place, September 24, from heart disease.

George Schoonover (license, Kansas, 1901); said to have been the oldest practitioner of Anderson County; died at his home in Garnett, October 4, aged 78.

Joseph M. Perry, M.D. Medical College of the State of South Carolina, Charleston, 1860; formerly of Lakeland, Fla.; died at his home in Pensacola, September 19.

Joseph Penn Cheney, M.D. University of Maryland, Baltimore, 1852; died at his home in Breathedsville, Md., October 3, from senile debility, aged 80.

John Daniel Lavery (license, eighteen years of practice, Michigan, 1900); died at his home in Mount Pleasant, Mich., June 7, from paralysis, aged 69.

James W. Fletcher, M.D. Cincinnati College of Medicine and Surgery, 1861; died at his home near Rufus, Ky., Oct. 9, 1910, from senile debility, aged 72.

Felix H. Johnson, M.D. Jefferson Medical College, 1869; died at his home in Gainesville, Texas, October 4, from disease of the stomach, aged 65.

Charles M. Hoag, M.D. Eclectic Medical Institute, Cincinnati, 1907; died in his home in Judsonia, Ark., August 19, from typhoid fever, aged 29.

Charles Edward Stammler, M.D. College of Physicians and Surgeons, New York City, 1885; died at his home in Brooklyn, September 28, aged 56.

John A. Francis, M.D. Medical College of Ohio, Cincinnati, 1868; died recently at his home in Covington, Ky., and was buried October 3, aged 66.

James Fair, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1883; died at his home in New Paynesville, Minn., in August.

Herbert L. Atkins, M.D. Medical College of Virginia, Richmond, 1893; died at his home in Boydton, Va., July 20.

William M. Murdock (license, North Carolina, 1876); died at his home in Balsam, April 13, from heart disease.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession.

CONVICTIONS UNDER THE FOOD AND DRUGS ACT *

(Continued from page 1385)

NICHOLS' COMPOUND KOLA CORDIAL

This drug was made by Billings, Clapp & Co., Boston, who claimed that it contained:

Kola Nut	40	grains.
Coca Leaves	40	grains.
Strychnin	1/50	grain.
Alcohol	20	per cent.
Cocain, in each ounce	0.2	

The product was declared misbranded because, while it was labeled "Nichols' Compound Kola Cordial," it was not manufactured by Nichols and it was not kola; further it did not contain 20 per cent. alcohol and neither did it contain the proportion and amounts of cocain, kola nut, coca leaves or strychnin, which the label represented it to contain. The company first pleaded not guilty but later changed its mind, and was fined $25.—[*Notice of Judgment, No. 909.*]

HARRIS' LITHIA WATER

"Nature's Remedy—Harris' Lithia Water, for the liver, kidneys, stomach and the bladder, and all affections attendant on a uric acid condition" was offered for sale in the District of Columbia. The label stated that:

> "This water is unequalled for the cure of rheumatism, gout, constipation, all forms of dyspepsia, stone in the bladder, catarrh of the stomach, Bright's disease," etc

The label also bore what purported to be a certified analysis in which the statement appeared that the water contained 2.86 grains of lithium bicarbonate to the gallon. The analysts in the Bureau of Chemistry found, however, that Harris' Lithia Water contained only about 1/830 grain of lithium to each gallon. The product was declared misbranded because it was not a lithia water and did not contain the amount of lithium bicarbonate given on the label. The consignee, Thomas H. Atkinson, of Washington, D. C., admitted the charges brought by the government. The court decided that the bottles of water might be returned to Atkinson after he had paid the cost of the proceedings and had given bond that the water should not be sold or disposed of contrary to law. [*Notice of Judgment, No. 924.*]

DR. ELDERS' CELEBRATED TOBACCO SPECIFIC

H. W. Elders of St. Joseph, Mo., shipped into the state of Michigan a quantity of a drug preparation having the name given above and under claims that were in part as follows:

---

* Descriptions of ninety convictions previously reported in popular form in The Journal are issued as an illustrated pamphlet, entitled "Convictions," price 6 cents.

> "Cures Smoking, Chewing, Cigarette and Snuff Dipping Habits in three to five days."
> "It is as Certain in its Cure as are Taxes and Death sure to all."
> "Oldest, Cheapest, Best. Thousands so testify."
> "A positive cure for the 'Tobacco Heart'."
> "Contains no injurious drugs or ingredients."

Analysis by the government chemists showed that the tablets consisted essentially of cocain and cocain derivatives, strychnin and cinchona alkaloids. The cocain, strychnin and cinchona alkaloids amounted to about 3/10 of 1 per cent. The remainder of the tablets consisted of sugar and starch with a small amount of ginger, the whole being flavored with artificial oil of wintergreen. As the tablets were not a specific for the tobacco habit and as it did contain "injurious drugs or ingredients," the product was declared misbranded. Elders pleaded guilty and was fined $100 and costs. [*Notice of Judgment, No. 930.*]

CHANDLER'S HEADACHE BUTTONS

Another typical headache mixture, each "button" containing 3½ grains of acetanilid as well as caffein. The label stated that it would cure rheumatism, nervous headache, neuralgia and other things "in fifteen minutes." This, of course, was an untruth and the stuff was declared misbranded. The Chandler Medicine Company of St. Louis, who distributed this stuff, pleaded guilty and was fined $10 and costs. [*Notice of Judgment, No. 931.*]

SABINE'S BLACKBERRY SOOTHING DROPS

A preparation of this name was shipped by the A. J. Lemke Medicine Company of Milwaukee into another state. It was labeled as a "cure" for diarrhea, dysentery, colic and cramps, and pain in the stomach and was recommended for "summer complaint" and teething children. Analyzed by the government chemists, it was found to contain nearly 10 per cent. of alcohol with glycerin, sugar and oil of cassia. The nostrum was declared misbranded because of the falsity of the therapeutic claims and because the proportion of alcohol was not given. The defendant pleaded guilty and was fined $10. [*Notice of Judgment, No. 933.*]

VANI-KOLA COMPOUND SYRUP

This was a soft drink preparation made by the Vani-Kola Company of Canton, Ohio. Analysis disclosed the presence of cocain and caffein and the product was therefore deemed adulterated in that it contained deleterious ingredients. It was also declared misbranded because the quantity or proportion of cocain was not given on the label. The company was fined $25 and costs after entering a plea of nolo contendere. [*Notice of Judgment, No. 935.*]

WHITE'S HEADEASE

O. P. White of Rusk, Texas, made and sold a liquid "headache cure" which contained acetanilid, alcohol and caffein. According to the label, it "contains no . . . enslaving drugs." The jury before whom the case was tried agreed with the Department of Agriculture that acetanilid and caffein are enslaving drugs and the product was therefore misbranded. White was fined $25. [*Notice of Judgment, No. 941.*]

AMMON PHENYL

Salvadore Penny, doubtless feeling that his own name was not sufficiently imposing, did business under the style International Chemical Company, Palisades Park, New Jersey. Mr. Penny was engaged in a business that used to be very popular among a certain class of self-styled pharmaceutical manufacturers, *namely, that of selling a simple acetanilid mixture* under a pseudo-scientific and sonorous title. "Ammon Phenyl" was said to be:

> "Antipyretic Antiseptic, Antineuralgic, Antiseptic Puritas et Potentia, Non Plus Ultra Stimulant, Laxative . . . For Physicians' Prescriptions only . . . Ammoniated Pheno Acetyl, $C_6H_5NH_2$."

> "Ammon Phenyl is one of the acetyl derivatives of anilin of the Amido-Benzene Series whose base is $C_6H_5NH_2$, combined by our own special chemical process with ammonia. The presence of ammonia tends to overcome the depressing effects usually observed in other Coal Tar derivatives . . . "

And a great deal more pseudo-scientific nonsense of the same type. A sample of this wonderful chemical was analyzed by the government chemists and found to be a mere mixture of:

Acetanilid
Sodium bicarbonate
Ammonium bicarbonate

This headache remedy was declared misbranded because of the attempt on the part of the manufacturer to obscure the origin or nature of the product and make it appear that this simple mixture was a chemical compound. The inference given that the mixture did not produce the depressing effects of acetanilid was also false and misleading. In addition to this the therapeutic claims were declared false. Penny entered plea of non vult and was fined $25. [*Notice of Judgment, No. 942.*]

SMITH'S QUININETS

Smith's Quininets were sold by C. E. Rupert Smith of Philadelphia. It was labeled as "a sure cure and preventive" for a long list of ailments, although analysis showed it to consist essentially of a mixture of quinin and acetanilid. The product was declared misbranded because of the false therapeutic claims. Smith pleaded guilty and was fined $5. [*Notice of Judgment, No. 965.*]

BUCKHEAD LITHIA WATER

This water shipped by the Buckhead Springs Company of Buckhead, Virginia, was another lithia water that did not contain any measurable quantity of lithia. It was declared misbranded and as no one appeared to claim it, the courts ordered its destruction. [*Notice of Judgment, No. 968.*]

WALKER'S TONIC

Walker's Tonic Company and Sam Dreyfuss, both of Paducah, Ky., shipped a consignment of this preparation to Tennessee. It was sold as a "brain food," "heart tonic," "stomachic" and "liver regulator," and was a nostrum of the cure-all type. When analyzed, it was found to consist essentially of 18.21 per cent. alcohol, 4.02 per cent. non-volatile material, including capsicum, celery, an emodin-bearing drug and other drug extractives, the balance of the product being water. It was declared misbranded because of the falsity of the therapeutic claims. The defendant pleaded guilty and was fined $25 and costs.—[*Notice of Judgment, No. 982.*]

HAARLEM OIL CAPSULES

This product sold by the Holland Medicine Company, Scranton, Pa., was labeled "Genuine Haarlem Oil Capsules." Analysis by federal chemists showed that the preparation contained methyl salicylate which is not a normal ingredient of Haarlem oil. Various false and extravagant claims were made for the nostrum. It was declared misbranded because of the therapeutic claims and because of the presence of methyl salicylate. A plea of nolo contendere was entered by the defendant and the court imposed a fine of $10 and costs.—[*Notice of Judgment, No. 987.*]

HUMBUG OIL

Humbug Oil was the expressive and truthful title given to a nostrum shipped by Mrs. J. F. Marshall Smith of Minnesota to Utah. If no other claim than that denoted by its name had been made, Mrs. Smith could doubtless have continued to sell her nostrum unmolested. It was said, however, to "relieve diphtheria of the most malignant type." The government chemists reported that Humbug Oil consisted essentially of 20 per cent. oil of turpentine, 20 per cent. linseed oil and the balance a watery-alcoholic solution of ammonia water, ammonium salts and a volatile alkaloid, probably coniin. While the stuff was undoubtedly a humbug, it would not "relieve diphtheria of the most malignant type" and was therefore declared misbranded. The defendant was fined $5 after entering a plea of guilty.—[*Notice of Judgment, No. 988.*]

DR. MOFFETT'S TEETHINA

T. N. Flourney, who does business in St. Louis under the name of C. L. Moffett Medicine Company, shipped a consignment of Dr. Moffett's Teethina into another state. Analysis of this preparation showed the product to be a powder consisting essentially of:

Opium.
Calcium carbonate.
Calomel.
Powdered cinnamon.

This mixture was said to aid digestion, heal eruptions and sores, prevent a tendency to colic, remove and prevent worms in children, strengthen the child and make teething easy—and to do several other things. All of these claims were declared false by the government officials and on that ground the preparation was declared misbranded. Flourney pleaded guilty and was fined $10 and costs.—[*Notice of Judgment, No. 1019.*]

FITCH RHEUMATIC CURE

The Fitch Remedy Company of Racine, Wis., made this stuff, which was "guaranteed to cure the most stubborn case of sciatic or muscular rheumatism." The government chemists reported that it was found to consist essentially of rhubarb and alcohol. False therapeutic claims were the basis of the charge of misbranding brought by the government. The defendant pleaded guilty and paid the $10 fine that was imposed.—[*Notice of Judgment, No. 1024.*]

CERRODANIC CAPSULES

Samuel H. Jameson, who did business at Decatur, Ill., under the firm name of The Cerrodanic Company, made the following claims on the label of his nostrum:

"A positive cure for rheumatism."
"We are the first to discover the true cause of rheumatism."
"A radical and certain cure of this dreaded disease."

The capsules were reported by the government chemists to contain sodium salicylate, potassium nitrate and charcoal, together with a small amount of chloroform extract, containing capsicum and an unidentified oily substance and a large amount of talc and the carbonates and oxids of sodium and potassium. Because the therapeutic claims made for this preparation were false, it was declared misbranded. Jameson pleaded guilty and was fined $10 and costs.—[*Notice of Judgment, No. 1025.*]

Correspondence

Eliminate the Term "Allopath"

To the Editor:—The following correspondence speaks for itself:

Mr. Joseph W. Hill, President,
Atlanta City Directory Company,
Atlanta, Ga.

Dear Sir:—In recent issues of the "Atlanta City Directory," the medical practitioners of the city have been classified as "Allopathic," "Homeopathic," "Eclectic," etc., and at a regular meeting of the Fulton County Medical Society, the undersigned were appointed a committee to confer with you, as president of the directory company, in regard to this classification.

Medical men may be divided into two grand classes—physicians and practitioners of exclusive systems. The adherents of the several systems which have come into existence from time to time, and some of which are now represented in this country, have adopted certain distinctive terms to designate their peculiar practice and to distinguish them from the great body of educated and scientific physicians who belong to no sect, affiliate with no "school," accept no dogma, acknowledge no creed and recognize no arbitrary limit in their practice of the healing art.

To the employment of nicknames on the part of these seceders we urge no objection, and in the use of such names by them—whatever may be their object—we have no concern. Their segregation is voluntary, and the names selected by themselves, it is presumed, are appropriate and agreeable to them.

This is not true, however, of the attempt to fix the name "allopathic" on the reputable physicians of the country. Any such epithet is objectionable and offensive to them, and is repugnant to truth. They are physicians—regular physicians, if you prefer—and it is impossible to apply a qualifying term that appropriately describes their status. They hold that it is inconsistent with the dignity of a learned and honored profession to be designated by a nickname or by any appellation of restrictive significance, and that it is entirely at variance with propriety and the facts to describe their faith or practice by a word, when they are not, in any manner, bound or limited in their views of disease, the selection of remedies or the application of remedial agents.

No descriptive term, therefore, is necessary, and none is available. They cannot properly be circumscribed, hedged in or defined. Physicians are the disciples of the whole science and art of medicine in its widest and most comprehensive sense—nothing more and nothing less—without any real or professed limitations, whatsoever.

We feel confident that, on reflection and investigation, you will coincide with these views and that you will accede to our request to eliminate, as misleading, unnecessary and unjust, this distasteful feature of your excellent work.

Awaiting your answer, we are

Yours very truly,
James B. Baird, M.D.,
John C. Olmsted, M.D.,
L. P. Stephens, M.D.,
Committee.

Dr. J. B. Baird, Chairman Committee,
Fulton County Medical Society, City.

Dear Sir:—Replying to your recent favor requesting that we discontinue the use of the term "allopath," as applied to the medical fraternity belonging to your school of medicine, beg to say that it will afford us great pleasure to comply with your request.

In publishing the city directory, it is our chief aim to give satisfaction to everybody and to be accurate in our statements.

With kindest regards, we are

Yours very truly,
Atlanta City Directory Company.
Per Joseph W. Hill.

I am informed that the objectionable term "allopathic" is in general use throughout the country among directory publishers, and I believe the medical profession should make determined resistance to the obnoxious practice. It is doubtless largely the result of ignorance on the part of publishers—an ignorance which also involves the general public and even some reputable medical men.

It will be a gracious and profitable move on the part of The Journal with its wide influence to take cognizance of this question.

James B. Baird, Atlanta, Ga.

Antifat and Society Women

To the Editor:—An editorial in The Journal, entitled "Antifat and Society Women" (Oct. 14, 1911, p. 1290), induces me to report the following, showing a dangerous effect of thyroid: About five years ago a woman, aged 42, came to me complaining that in bright light she had difficulty in seeing, all objects appearing more or less hazy; but in a subdued light, or even in comparative darkness she had no trouble. An ophthalmoscopic examination showed an apparently normal fundus, with the possible exception of slight blurring of the edges of the disk. The vision was 2/3 of normal in each eye. Perimetric examination disclosed an oval central scotoma for red and green in both eyes. Investigation of her mode of life revealed no apparent cause for this condition; she denied being addicted to either tobacco or alcohol. Repeated examination disclosed no sugar in the urine, this being the most frequent cause of a chronic toxic amblyopia, such as she was suffering from. Quite accidentally, during a subsequent examination, she volunteered the information that for a number of months she had been taking an antifat remedy recommended by a friend. Investigation revealed the fact that this patient had been taking thyroid extract for almost three months to reduce her weight. The thyroid was at once stopped; the patient was given strychnin hypodermatically, and in a few weeks the scotoma disappeared. On searching the literature at that time, I found one similar case reported by Albertsberg (*Arch. f. Augenh.* [Knapp's], January, 1904, p. 86), who cites four cases reported by Coppez. Whether any cases have been reported since that time, I am unable to say.

Emanuel F. Snydacker, Chicago.

Low Sanitary Standards in Rural Communities

To the Editor:—A Current Comment in The Journal (Oct. 7, 1911, p. 1214) leads me to describe the *status quo* of the town in which I am practicing. No doubt there are numerous parallel cases which literally "smell to heaven," while eliciting no reaction in the obtuse sensibilities of human beings. Our community has about 2,000 inhabitants, but is not incorporated, being part of the township government. It has been built up alongside a foundry which employs nearly all the men of the place; the owners of the foundry

"Cures Smoking, Chewing, Cigarette and Snuff Dipping Habits in three to five days."

"It is as Certain in its Cure as are Taxes and Death sure to all."

"Oldest, Cheapest, Best. Thousands so testify."

"A positive cure for the 'Tobacco Heart'."

"Contains no injurious drugs or ingredients."

Analysis by the government chemists showed that the tablets consisted essentially of cocain and cocain derivatives, strychnin and cinchona alkaloids. The cocain, strychnin and cinchona alkaloids amounted to about 3/10 of 1 per cent. The remainder of the tablets consisted of sugar and starch with a small amount of ginger, the whole being filavored with artificial oil of wintergreen. As the tablets were not a specific for the tobacco habit and as it did contain "injurious drugs or ingredients," the product was declared misbranded. Elders pleaded guilty and was fined $100 and costs. [*Notice of Judgment, No. 930.*]

CHANDLER'S HEADACHE BUTTONS

Another typical headache mixture, each "button" containing 3½ grains of acetanilid as well as caffein. The label stated that it would cure rheumatism, nervous headache, neuralgia and other things "in fifteen minutes." This, of course, was an untruth and the stuff was declared misbranded. The Chandler Medicine Company of St. Louis, who distributed this stuff, pleaded guilty and was fined $10 and costs. [*Notice of Judgment, No. 931.*]

SABINE'S BLACKBERRY SOOTHING DROPS

A preparation of this name was shipped by the A. J. Lemke Medicine Company of Milwaukee into another state. It was labeled as a "cure" for diarrhea, dysentery, colic and cramps, and pain in the stomach and was recommended for "summer complaint" and teething children. Analyzed by the government chemists, it was found to contain nearly 10 per cent. of alcohol with glycerin, sugar and oil of cassia. The nostrum was declared misbranded because of the falsity of the therapeutic claims and because the proportion of alcohol was not given. The defendant pleaded guilty and was fined $10. [*Notice of Judgment, No. 933.*]

VANI-KOLA COMPOUND SYRUP

This was a soft drink preparation made by the Vani-Kola Company of Canton, Ohio. Analysis disclosed the presence of cocain and caffein and the product was therefore deemed adulterated in that it contained deleterious ingredients. It was also declared misbranded because the quantity or proportion of cocain was not given on the label. The company was fined $25 and costs after entering a plea of nolo contendere. [*Notice of Judgment, No. 935.*]

WHITE'S HEADEASE

O. P. White of Rusk, Texas, made and sold a liquid "headache cure" which contained acetanilid, alcohol and caffein. According to the label, it "contains no . . . enslaving drugs." The jury before whom the case was tried agreed with the Department of Agriculture that acetanilid and caffein are enslaving drugs and the product was therefore misbranded. White was fined $25. [*Notice of Judgment, No. 941.*]

AMMON PHENYL

Salvadore Penny, doubtless feeling that his own name was not sufficiently imposing, did business under the style International Chemical Company, Palisades Park, New Jersey. Mr. Penny was engaged in a business that used to be very popular among a certain class of self-styled pharmaceutical manufacturers, namely, that of selling a simple acetanilid mixture under a pseudo-scientific and sonorous title. "Ammon Phenyl" was said to be:

> "Antipyretic Antiseptic, Antineuralgic, Antiseptic Puritas et Potentia. Non Plus Ultra Stimulant, Laxative . . . For Physicians' Prescriptions only . . . Ammoniated Pheno Acetyl, $C_6H_5NH_2$."

> "Ammon Phenyl is one of the acetyl derivatives of anilin of the Amido-Benzene Series whose base is $C_6H_5NH_2$, combined by our own special chemical process with ammonia. The presence of ammonia tends to overcome the depressing effects usually observed in other Coal Tar derivatives . . . "

And a great deal more pseudo-scientific nonsense of the same type. A sample of this wonderful chemical was analyzed by the government chemists and found to be a mere mixture of:

Acetanilid
Sodium bicarbonate
Ammonium bicarbonate

This headache remedy was declared misbranded because of the attempt on the part of the manufacturer to obscure the origin or nature of the product and make it appear that this simple mixture was a chemical compound. The inference given that the mixture did not produce the depressing effects of acetanilid was also false and misleading. In addition to this the therapeutic claims were declared false. Penny entered plea of non vult and was fined $25. [*Notice of Judgment, No. 942.*]

SMITH'S QUININETS

Smith's Quininets were sold by C. E. Rupert Smith of Philadelphia. It was labeled as "a sure cure and preventive" for a long list of ailments, although analysis showed it to consist essentially of a mixture of quinin and acetanilid. The product was declared misbranded because of the false therapeutic claims. Smith pleaded guilty and was fined $5. [*Notice of Judgment, No. 965.*]

BUCKHEAD LITHIA WATER

This water shipped by the Buckhead Springs Company of Buckhead, Virginia, was another lithia water that did not contain any measurable quantity of lithia. It was declared misbranded and as no one appeared to claim it, the courts ordered its destruction. [*Notice of Judgment, No. 968.*]

WALKER'S TONIC

Walker's Tonic Company and Sam Dreyfuss, both of Paducah, Ky., shipped a consignment of this preparation to Tennessee. It was sold as a "brain food," "heart tonic," "stomachic" and "liver regulator," and was a nostrum of the cure-all type. When analyzed, it was found to consist essentially of 18.21 per cent. alcohol, 4.02 per cent. non-volatile material, including capsicum, celery, an emodin-bearing drug and other drug extractives, the balance of the product being water. It was declared misbranded because of the falsity of the therapeutic claims. The defendant pleaded guilty and was fined $25 and costs.—[*Notice of Judgment, No. 982.*]

HAARLEM OIL CAPSULES

This product sold by the Holland Medicine Company, Scranton, Pa., was labeled "Genuine Haarlem Oil Capsules." Analysis by federal chemists showed that the preparation contained methyl salicylate which is not a normal ingredient of Haarlem oil. Various false and extravagant claims were made for the nostrum. It was declared misbranded because of the therapeutic claims and because of the presence of methyl salicylate. A plea of nolo contendere was entered by the defendant and the court imposed a fine of $10 and costs.—[*Notice of Judgment, No. 987.*]

HUMBUG OIL

Humbug Oil was the expressive and truthful title given to a nostrum shipped by Mrs. J. F. Marshall Smith of Minnesota to Utah. If no other claim than that denoted by its name had been made, Mrs. Smith could doubtless have continued to sell her nostrum unmolested. It was said, however, to "relieve diphtheria of the most malignant type." The government chemists reported that Humbug Oil consisted essentially of 20 per cent. oil of turpentine, 20 per cent. linseed oil and the balance a watery-alcoholic solution of ammonia water, ammonium salts and a volatile alkaloid, probably coniin. While the stuff was undoubtedly a humbug, it would not "relieve diphtheria of the most malignant type" and was therefore declared misbranded. The defendant was fined $5 after entering a plea of guilty.—[*Notice of Judgment, No. 988.*]

DR. MOFFETT'S TEETHINA

T. N. Flourney, who does business in St. Louis under the name of C. L. Moffett Medicine Company, shipped a consignment of Dr. Moffett's Teethina into another state. Analysis of this preparation showed the product to be a powder consisting essentially of:

Opium.	Calomel.
Calcium carbonate.	Powdered cinnamon.

This mixture was said to aid digestion, heal eruptions and sores, prevent a tendency to colic, remove and prevent worms in children, strengthen the child and make teething easy—and to do several other things. All of these claims were declared false by the government officials and on that ground the preparation was declared misbranded. Flourney pleaded guilty and was fined $10 and costs.—[*Notice of Judgment, No. 1019.*]

FITCH RHEUMATIC CURE

The Fitch Remedy Company of Racine, Wis., made this stuff, which was "guaranteed to cure the most stubborn case of sciatic or muscular rheumatism." The government chemists reported that it was found to consist essentially of rhubarb and alcohol. False therapeutic claims were the basis of the charge of misbranding brought by the government. The defendant pleaded guilty and paid the $10 fine that was imposed.—[*Notice of Judgment, No. 1024.*]

CERRODANIC CAPSULES

Samuel H. Jameson, who did business at Decatur, Ill., under the firm name of The Cerrodanic Company, made the following claims on the label of his nostrum:

> "A positive cure for rheumatism."
> "We are the first to discover the true cause of rheumatism."
> "A radical and certain cure of this dreaded disease."

The capsules were reported by the government chemists to contain sodium salicylate, potassium nitrate and charcoal, together with a small amount of chloroform extract, containing capsicum and an unidentified oily substance and a large amount of talc and the carbonates and oxids of sodium and potassium. Because the therapeutic claims made for this preparation were false, it was declared misbranded. Jameson pleaded guilty and was fined $10 and costs.—[*Notice of Judgment, No. 1025.*]

Low Sanitary Standards in Rural Communities

To the Editor:—A Current Comment in THE JOURNAL (Oct. 7, 1911, p. 1214) leads me to describe the *status quo* of the town in which I am practicing. No doubt there are numerous parallel cases which literally "smell to heaven," while eliciting no reaction in the obtuse sensibilities of human beings. Our community has about 2,000 inhabitants, but is not incorporated, being part of the township government. It has been built up alongside a foundry which employs nearly all the men of the place; the owners of the foundry hold title to a large section of the dwellings. There is no sewer system and no public water-supply, a matter of surprise in view of the fact that the inhabitants are mostly American-born. In three squares of the section owned by the foundry authorities, the water-closets are without vaults and all overflow into open drains in the rear alleys, from which the contents are carted away at irregular intervals. In three other squares of this section the water-closets abut on and overflow into the streets. The supply of drinking-water of the residents of this section comes from wells in close proximity to these outhouses. A one-room school housing seventy pupils, with a triangular playground about 40 feet in its greatest dimension, is situated directly between and separates these two sections. The health standards in this place are markedly low, but the place is lacking in representative citizens informed and disinterested enough to demand redress. There is a local board of health, but it fails to act in the matter. An appeal to the state board of health elicits the information that it has no power to act in cases in which the nuisance is not a proved source of contagion. I believe that, for the proper application of the remedies suggested in the Current Comment, a radical broadening of the power of state health boards is demanded, since the members of local boards are usually incompetent to deal efficiently with questions of sanitation. Philip J. Dorety, M.D., Florence, N. J.

Thrombosis of the Mesentery Diagnosed Before Death

To the Editor:—I take exception to the statement of Dr. R. W. Wakefield in his article, "Thrombosis of the Mesentery," etc. (The Journal, Oct. 14, 1911, p. 1286), that "thrombosis of the mesentery . . . is never diagnosed, except at operation or post mortem." I recall a case in which I made a necropsy several years ago at the University Hospital, in which an ante-mortem diagnosis was correctly made by Dr. Alfred Stengel. The most striking of the symptoms was sudden severe abdominal pain. Autopsy revealed a thrombus in the superior mesenteric artery close to its origin, with corresponding segmental gangrene of the ileum.

Penn G. Skillern, Jr., Philadelphia.

Postoperative Constipation

I cannot agree with Dr. S. T. Pope (The Journal, October 21, p. 1359) that postoperative constipation is not harmful, or that it never causes auto-intoxication. In September a case in the Akron City Hospital after operation (performed for me by a surgeon) resulted in stasis of the intestine. The following failed to produce a movement: castor oil, enemata, aloin-belladonna-strychnin-cascara pills, cascara alone, phenolphthalein, etc., all repeated several times. Meanwhile the temperature climbed up day by day to over 103 F. Finally, twelve ounces of fluid citrate of magnesia did the work, and the temperature dropped to normal.

A. S. McCormick, Akron, O.

Queries and Minor Notes

Anonymous Communications will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DEFINITION OF THE WORD MORON

To the Editor:—In some recent medicolegal data I have seen used several times the word "moron." In consulting medical dictionaries and medicolegal works, I have not found a satisfactory definition. It seems to be derived from the Greek word *μωρία*, meaning madness, dementia or folly. Please give the accepted definition of the word. E. Moore Fisher, M.D., Wilmington, Del.

Answer.—Moron is a term applied in the classification of feeble-minded or subnormal children and indicates a high-grade feeble-minded child as distinguished from the imbecile or the idiot. The word, as our correspondent surmises, is from the same root as the Greek *μωρία*, folly, deing derived from the adjective *μωρός*, foolish. The English word "fool," as formerly used, describes exactly the individual designated by the term moron. Defectives have been divided into three classes: (1) those who never advance beyond the mental age of 3—these are the idiots; (2) those so retarded that they never advance beyond the mental age of 7—these are the imbeciles; (3) those so retarded that they never advance beyond the mental age of 12—these were formerly classed as high-grade feeble-minded children, but are now designated as "morons." Such children, if sufficiently high-grade to be sent to school, will always be behind and will reach their final mental development at the 12-year-old level. The moron can be trained to do a great many things but can never be made normal nor competent to take care of himself without direction. It is said that statistics show that from 1 to 2 per cent. of all school children belong to this type of feeble-minded. In a study of nearly 10,000 feeble-minded children, H. H. Goddard ("Subnormal Children," *Training School*, September, 1910) finds that the morons not only are subnormal mentally but show decided deviation from the normal in their growth. They cease growing from two to three years earlier than normal children, although this is not so apparent during the school age. As tested by the dynamometer, they have a capacity of from 20 to 30 per cent. of normal children. From among them come the dullards, and often the truants and incorrigibles.

PROCHOWNICK DIET IN PREGNANCY

To the Editor:—Please give details of the Prochownick diet and indications for its use. F. W. L.

Answer. For patients threatened with dystocia on account of a contracted pelvis, excessive development of the fetus with normal pelvis or fat and weak abdominal walls, Prochownick proposed a diet for the last eight weeks of pregnancy which should decrease the size and weight of the child, while strengthening the mother. The essential features of the diet are the withholding of carbohydrates and fluids and the giving of sufficient amounts of proteids. It is practically an antifat diet.

The following is the daily bill of fare:

Morning, one small cup of coffee without sugar; a small, thin piece of bread (¾ of an ounce).

Noon, all kinds of meat, fish without sauces, eggs, a little green vegetables, salad and cheese.

Evening, same as at noon, one medium piece of bread (1½ ounces) butter, eggs and meat.

If the patient is accustomed to the use of alcohol, a small bottle of red or white wine is allowed, or an equal quantity of water may be taken during the day.

Large quantities of liquids, soups, potatoes, desserts, sugar, etc., are forbidden.

Such a diet provides about 125 gm. of proteids giving 500 calories; 100 gm. of carbohydrates having 400 calories and 100 gm. of fat having 900 calories or in all about 1,800 calories a day.

Fat patients with weak muscles improve physically and mentally on this diet and come to labor in a much improved condition. As to the effect on the child, Prochownick and his followers assert that it will weigh a pound less than it would in the absence of the diet. The fat of the new-born, which amounts to 1 or 2 pounds, is laid on during the last eight weeks of pregnancy; the diet prevents this fat deposit. The child looks wrinkled, the head sutures are larger, and the head molds much better in its passage through the obstetric canal.

While the favorable effect of the diet is acknowledged by all, the results reported by Prochownick and a number of other good observers are such as to justify its adoption in proper cases. It is indicated, as already intimated, in women who are not very thin and anemic and who have a moderately contracted pelvis, conjugata vera between 8.5 and 10 cm., and especially in such multiparæ who have had a difficult labor. It is also indicated in a woman with a normal pelvis who has previously had a very large child and hard labor. Likewise it is indicated in a woman who has fat, weak muscles in whom dystocia may be expected due to insufficiency of the forces of labor.

The Public Service

Medical Officers, U. S. Army

Changes during the week ended Oct. 21, 1911.

Feely, James F., acting dental surgeon, left his home, Philadelphia, October 13, for his station, Ft. Slocum, N. Y.

McIntyre, H. B., captain, left Ft. Caswell on leave of absence for three months.

Fuffner, E. L., major, returned to Ft. Missoula from leave of absence.

Sheckley, M. A. W., major, on arrival of the *Sherman* will accompany the 146 C. A. to Ft. H. G. Wright, N. Y., then proceed to his station, Ft. Niagara.

Griffin, A. M., M.R.C., on arrival of the *Sherman* will accompany the 2nd Battery 20th Inf. to Ft. *Douglas, Utah, then proceed to* his station, Ft. Riley, Kan.

Mason, G. L., dental surgeon, reports his arrival at Ft. Omaha, Neb.

Heterick, R. H., lieut., reports his return to Ft. Brady, Mich., from leave of absence.

Bushnell, G. E., colonel, reports his departure from the Army General Hospital, Ft. Bayard, N. M., on thirty days' leave.

Sherwood, C. E., acting dental surgeon, reports his departure from Greenfield, Mass., for Columbus Barracks, O. (to obey his first order).

Feely, James F., acting dental surgeon, reports arrival at Ft. Slocum, N. Y., for duty.

Garcia, L. C., lieut., granted leave of absence for three months on surgeon's certificate of disability.

Boehs, C. J., M.R.C., returned from duty at Plattsburg Barracks, N. Y., and order to Ft. Banks, Mass., for duty.

Sanford, J. L., M.R.C., relieved from duty at Ft. Ruger, H. T., and will sail on the transport leaving Manila Oct. 15, 1911, for San Francisco, and on arrival will proceed to his home and stand relieved from active duty in the M.R.C.

Griffin, A. M., M.R.C., granted leave of absence for one month and twenty days, with permission to apply for an extension of one month, to take effect on relief from duty with troops at Ft. Douglas, Utah.

Crosby, W. D., lt.-col., left Soldiers' Home, Washington, D. C., for Army and Navy General Hospital, Hot Springs, Arkansas, for treatment.

Greenleaf, H. S., major, granted leave of absence for three months.

Sherwood, C. E., acting dental surgeon, reports his arrival at Columbus Barracks, Ohio, for duty.

Wing, F. F., dental surgeon, left Ft. D. A. Russell, Wyo., for Ft. Lincoln, N. D., for temporary duty.

Holmberg, C. E., lieut., returned to Ft. Bayard, N. M., from leave of absence.

Brooke, Roger, major, arrived in the U. S. and reported for duty at the U. S. Army General Hospital, Presidio of San Francisco.

Weed, M. D., lieut., returned from duty on the *Sherman* and assigned to duty on the *Thomas* as surgeon.

Huber, E. G., lieut., granted leave for one month about Oct. 15, and authorized to await at Nagasaki the arrival of the transport to leave Malla Nov. 15, 1911.

Parce, A. D., lieut., granted leave of absence for one month and fifteen days about Oct. 4, 1911, and authorized to await at Nagasaki the arrival of the transport to leave Manila Nov. 15, 1911.

Medical Corps, U. S. Navy

Changes during the week ended Oct. 21, 1911.

Miller, O. J., acting asst.-surg., appointment revoked from Oct. 21, 1911.

Tolfree, H. M., surgeon, detached from the navy recruiting station, Atlanta, Ga., and ordered to duty at the naval hospital, Norfolk, Va.

Jenness, B. F., P. A. surgeon, detached from the naval hospital, Norfolk, Va., and ordered to the navy recruiting station, Atlanta, Ga.

Stuart, M. A., P. A. surgeon, detached from the *Franklin* and ordered to duty at the naval hospital, Norfolk, Va.

Mann, Jr., W. L., asst.-surg., detached from the *Tennessee* and ordered to the *Hannibal*.

Stone, E. P., medical inspector, detached from duty at the naval hospital, Canacao, P. I., and ordered to naval hospital, Mare Island, Cal., for treatment.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF POSTGRADUATE WORK, CONTRACT PRACTICE, LEGISLATION, MEDICAL DEFENSE, AND OTHER MEDICOLEGAL AND ECONOMIC QUESTIONS OF INTEREST TO PHYSICIANS

NEWSPAPER ENDORSEMENTS OF NATIONAL HEALTH LEGISLATION

The newspapers are giving an increasing amount of space to the endorsement of public health legislation. The duty of the state to protect the public health is now being urged by many of our leading dailies and sentiment is rapidly growing in all parts of the country in favor of advanced state activity on this subject. It is only possible to reprint an occasional newspaper editorial, from time to time, for the information of the readers of THE JOURNAL. A recent issue of the Spokane *Review* contained an excellent editorial entitled:

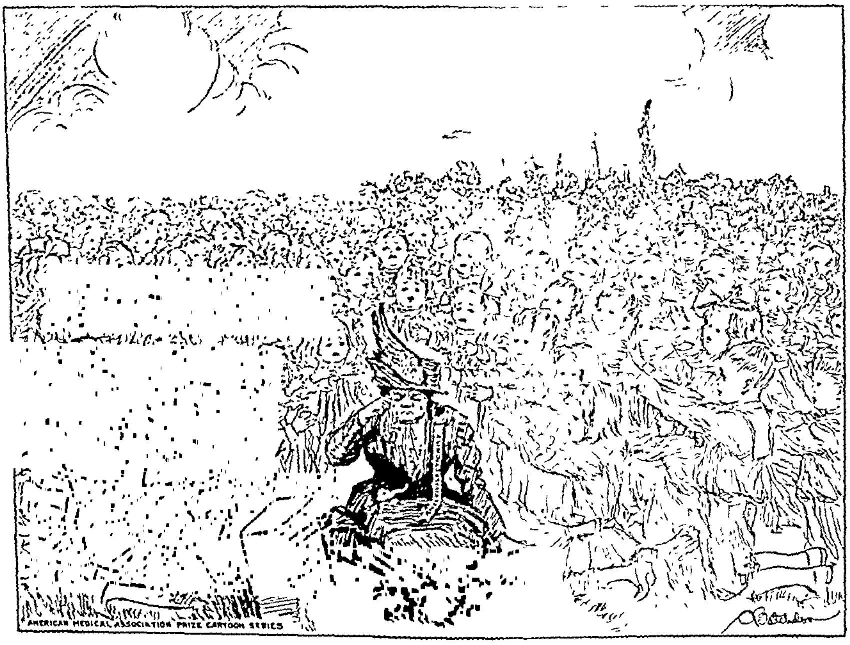
CARE OF HEALTH FALLS WELL WITHIN THE SPHERE OF THE STATE

"The American Medical Association pursues a statesmanlike policy in pushing doctors into the lecturing field as apostles of the gospel of health and of national conservation of human health.

"The *Spokesman-Review* has always accepted the view expressed by Gladstone that the care of health, both that of the individual and that of the community, falls well within the sphere of the state and the legitimate functions of the government.

"*A great authority on the value of man said that he is of infinite worth. Economists have estimated the* annual cost of avoidable diseases to a country as amounting to millions on millions of money. But governments expend immense amounts *on preventing dis*ease among the animals used by men and practically nothing to avoid the needless diseases of human beings.

"This is putting the cart before the horse. It betrays an *inverted* sense of relative values. If the *national government* has in ten years spent $40,000,000 to protect the health of crops and animals *it may logically and* consistently be expected to spend more for the health of the toiling men and loving women and dear children, that are worth infinitely more than grains, fruits, donkeys and cows."



AMERICAN MEDICAL ASSOCIATION PRIZE CARTOON SERIES

"PUPPY LOVE" vs. LOVE FOR HUMANITY

FALSE SENTIMENT CANNOT PREVAIL AGAINST THE PLEA OF HUMAN LIFE.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

[NOTE.—The pamphlets containing the outline of the postgraduate study course for county societies for the coming year are ready for *distribution*. Secretaries of county societies can secure supplies by writing to the Secretary, Council on Health and Public Instruction, American Medical Association, 535 Dearborn Ave., Chicago.]

Second Month—Fourth Weekly Meeting

ACUTE TRAUMATIC ABSCESS OF BRAIN[1]

PATHOLOGY: Compound fracture, injury to meninges and cortex, character and quantity of pus, changes in meninges and cortex, granulation and cicatrization.

---

[1] Starr: Medical Record, March 10, 1906. Spiller: Univ. of *Penn Med Bull.*, October, 1906. Ballance: *Surgery of the Brain.* Macewen: Brit. Med Jour., July 30, 1904.

SYMPTOMS: Local evidences of sepsis, pulse and temperature, focal symptoms. Differentiate from meningitis.

TREATMENT: Indications for operative treatment.

CHRONIC TRAUMATIC ABSCESS OF BRAIN

PATHOLOGY: Secondary to pus in skull, foreign bodies, ear, nose, thorax. By metastasis. Sinus-thrombosis. Location of abscess, abscess membrane, mode of extension, rate of growth.

SYMPTOMS: (1) Primary symptoms, cause and significance. (2) Latent period, length, usual symptoms. (3) Secondary symptoms. (4) Terminal period.

TREATMENT: Indications for exploring or trephining.

TUMORS OF BRAIN[2]: VARIETIES, PATHOLOGY AND INCIDENCE

General Symptoms: Headache, optic neuritis, vomiting, giddiness, mental disturbance. Papilledema.[3]

Localizing Symptoms: (a) Central motor area, signal symptom, extension, paralysis or anesthesia. (b) Prefrontal region, mental symptoms, later symptoms. (c) Parieto-occipital lobe, aphasia. (d) Occipital lobe. (e) Temporal lobe. (f) Basal ganglia. (g) Pons and medulla. (h) Cerebellum.

TREATMENT: Indications for cerebral decompression.[4]

Monthly Meetirg

Indications for Operative Treatment of Fractures of the Base of the Skull.

The Operability of Tumors of the Brain.

Indications for Cerebral Decompression and Technic.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

ARKANSAS: Regular, Little Rock, November 14. Sec., Dr. F. T. Murphy, Brinkley; Homeopathic, Little Rock, November 14. Sec., Dr. P. C. Williams, Texarkana.

CONNECTICUT: Regular, City Hall, New Haven, November 14. Sec., Dr. Charles A. Tuttle, 196 York Street; Homeopathic, Grace Hospital, New Haven, November 14. Sec., Dr. Edwin C. M. Hall, New Haven; Eclectic, Hotel Garde, New Haven, November 14. Sec., Dr. Thomas S. Hodge, 19 Main Street, Torrington.

FLORIDA: Regular, Jacksonville, November 7-8. Sec., Dr. J. D. Fernandez.

LOUISIANA: Homeopathic, New Orleans, November 13. Sec., Dr. J. T. Crebbin, 1207 Maison Blanche Building.

MAINE: City Council Rooms, Portland, November 14-15. Sec., Dr. F. W. Searle, 776 Congress Street.

MASSACHUSETTS: State House, Boston, November 14-16. Sec., Dr. Edwin B. Harvey.

NEVADA: Carson City, November 6. Sec., Dr. S. L. Lee.

TEXAS: Forth Worth, November 28. Sec., Dr. J. D. Mitchell.

WEST VIRGINIA: Hotel Waldo, Clarksburg, November 13-15. Sec., Dr. H. A. Barbee, Point Pleasant.

Kansas June Report

Dr. H. A. Dykes, secretary of the Kansas Board of Medical Registration and Examination, reports the written examination held at Topeka, June 13-15, 1911. The number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 66, of whom 46 passed and 20 failed, including one chiropractic. The following colleges were represented:

College PASSED	Year Grad.	Per Cent.
University of Colorado	(1911)	93
Howard University, Washington, D. C.	(1910)	92
Chicago College of Medicine and Surgery	(1911)	83
Illinois Medical College	(1910)	87
College of Physicians and Surgeons, Chicago	(1900)	91
University of Kansas	(1911)	77, 78, 80, 81, 83, 83, 86, 86, 87, 87, 87, 88, 88, 89, 90, 93.
Kansas Medical College	(1894) 78; (1911)	78, 80, 84, 84, 85, 85, 86, 87.

Nebraska August Report

Dr. E. Arthur Carr, secretary of the Nebraska State Board of Health, reports the written examination held at Lincoln, August 9-10, 1911. The number of subjects examined in was 8; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 15, of whom 14 passed and 1 failed. Nine candidates were licensed through reciprocity. The following colleges were represented:

College PASSED	Year Grad.	Per Cent.
College of P. & S., Chicago	(1892) 76.5; (1911)	78.5
University of Maryland	(1911)	84.5
Missouri Medical College	(1893)	87.5
Ensworth Medical College	(1911)	77.4
Lincoln Medical College	(1909) 89; (1911)	78.7
Creighton Medical College	(1911)	76.9, 82, 83, 87.5
Jefferson Medical College	(1901)	84.9
Meharry Medical College	(1911)	77.6
Marquette University	(1910)	89.2
FAILED		
Lincoln Medical College	(1911)	70.7

College LICENSED THROUGH RECIPROCITY	Year Grad.	Reciprocity with
University of Iowa, Homeopathic College	(1910)	Iowa

Book Notices

A Manual of Pathology and Morbid Anatomy. By T. Henry Green, M.D., F.R.C.P., Consulting Physician to Charing Cross Hospital, and to the Brompton Hospital for Consumption and Disease of the Chest. Eleventh Edition. Revised and Enlarged by W. Cecil Bosanquet, M.A., M.D., F.R.C.P., Assistant Physician (Late Pathologist) to Charing Cross Hospital and to the Brompton Hospital for Consumption and Diseases of the Chest. Cloth. Price, $4.50 net. Pp. 612, with 350 illustrations. Philadelphia: Lea & Febiger, 1911.

The alterations in the contents of this book since the last edition are not inconsiderable owing to the many noteworthy advances made in pathology since the last edition was published, six years ago. Much more space is given to the chapters on parasites and tumors and new matter is added, although it is rather doubtful whether the pathology of affections of the skin can be presented adequately in the few pages here allotted to this subject. Acne and psoriasis are the only two skin affections considered. Only half a page is given to the spleen and two pages to the lymph structures. The chapter on bone does not even mention fragilitas ossium or osteomyelitis, although tuberculous osteomyelitis is discussed in the chapter on tuberculosis. Rickets and achondroplasia are the only two conditions described under bone. One paragraph disposes of the pathology of the hypophysis cerebri. The adrenals and thymus are not mentioned. As for the joints, their pathology is disposed of in a two-page discussion of gouty and rheumatoid arthritis. The diseases of the blood are merely touched on. In fact, all that portion of the book, about 200 pages, devoted to the diseases of special tissues and organs is incomplete; many topics being omitted and others merely mentioned. The author has given most of his attention to parasites and tumors. They are discussed in a thorough and able manner. In short, as a book on general pathology this work possesses many admirable features; as a book on special pathology, it is not altogether satisfactory.

Practical Medical Chemistry for Physicians and Students. By Charles Platt, A.C., M.D., Ph.D., and William A. Pearson, Ph.C., Ph.D., Analytical and Consulting Chemist. Sixth Edition. Cloth. Price, $2.50 net Pp. 254. Philadelphia: John Jos. McVey, 1229 Arch Street, 1911.

This work is evidently intended to be a combination of encyclopedic text-book and laboratory manual. Apparently it endeavors to include a smattering of all of the knowledge of chemistry required by medical students and physicians. It is obvious that the numerous subdivisions of chemistry, an understanding of which is necessary to the physician, cannot be treated adequately in a work of this size. As an example of the inadequate treatment of the subject-matter, it may be mentioned that the general subject "glucosids" is disposed of in nine lines, notwithstanding that the glucosids are of constantly increasing importance in therapy and toxicology. More attention is devoted to urinalysis than to any other subject, the essentials of a moderately complete examination being given together with suggestions as to the clinical significance of the results obtained.

Meningitis, Sinus Thrombosis and Abscess of the Brain. With Appendixes on Lumbar Puncture and Its Uses and Diseases of the Nasal Accessory Sinuses. By John Wyllie, M.D., Author of "Tumors of the Cerebellum." Cloth. Price, $3 net. Pp. 258. New York: Paul B. Hoeber, 1911.

This little volume is written from the view-point of the internist and not from that of the surgeon, although the major part of it deals with purely surgical subjects. The first two chapters, on "Meningitis" and "Thrombosis of the Cerebral Sinuses," respectively, are rather meager and not very satisfactory. The chapter on "Intracranial Abscess" is much better and some useful points may be found under "Differential Diagnosis." The author, not being a surgeon, does not take up the treatment but says, "The only possible treatment is operation, the management of which does not form part of this work." Omitting therefore such an important phase of the subject, the work must prove more or less unsatisfactory to those consulting it. A brief appendix on "Lumbar Puncture" and one on "The Nasal Accessory Sinuses" concludes the volume.

Medicolegal

Religious Belief no Defense for Parent's Failure to Furnish Medical Treatment for Child

(Owens vs. State (Okla.) 116 Pac. R. 345)

The Criminal Court of Appeals of Oklahoma affirms a conviction of the defendant Owens of violating the law by wilfully omitting, without lawful excuse, to furnish medical attendance to his minor child. The court holds that, under the statutes of that state, it is the duty of a parent having the custody of a minor child to support and educate such child; that such "support" includes necessary medical attendance to preserve the health and life of such child; that a reasonable construction of the statutes requires the furnishing of medical treatment in such a manner and on such occasions as an ordinarily prudent person, solicitous for the welfare of his child and anxious to promote his recovery, would provide it.

In a prosecution for a violation of that section of the statutes which provides, "Every parent of any child who wilfully omits, without lawful excuse, to perform any duty imposed on him by law to furnish necessary food, clothing, shelter or medical attendance, for such child, is guilty of a misdemeanor," an instruction of the trial court that religious belief will not constitute a defense to such prosecution is correctly given. The question of the necessity for medical treatment is a question of facts for the jury in any case for the violation of the statute, and when submitted under proper instruction of the court a finding of the jury, contrary to the contentions of an accused, will not be disturbed on appeal, when the evidence tends reasonably to support the finding.

In this case it appeared that the defendant's child was afflicted with typhoid fever, and that the county health officer and other physicians and neighbors of the accused called on and endeavored to induce him to permit the child to be attended by physicians and nurses, and he refused to do so, even though the medical attendance was offered without expense. In the testimony of the accused, he admitted that he was acquainted with the serious nature of typhoid fever, and knew that his child was seriously ill, and offered no excuse for his conduct, but the testimony on behalf of the state, and by the mother of the child, who testified on behalf of the accused, disclosed that the reason for refusing to provide medical attendance was on account of religious belief.

The court says that, under the Oklahoma statutes, it is the duty of the parent, regardless of his religious belief or superstition, to furnish necessary food, clothing, shelter and medical attendance to his child. A reasonable construction of these statutes would be that the parent is required to furnish the necessary food, clothing, shelter and medical attendance looking to the preservation of the health, as well as the life, of the child. The law does not contemplate the calling of a physician or the furnishing of medical attendance for every trivial complaint with which a child may be afflicted. A reasonable amount of discretion is vested in the parents charged with the duty of maintaining and bringing up of infant children. As before stated, the correct rule would require the furnishing of medical treatment in such a manner and on such occasions as an ordinarily prudent person, solicitous for the welfare of his child and anxious to promote its recovery, would provide.

The proposition that religious belief constitutes no defense for violation of a penal statute has been repeatedly announced by the courts in construing various other statutes, principally the violation of statutes on Sabbath breaking. The reasons given in those cases support the position of the court in this case. If religious belief would be a defense to the violation of the statute quoted it would necessarily follow that it would be a defense to the violation of the statutes against Sabbath breaking, and the statutes against polygamous marriages, and various other wholesome penal laws.

In this case, every act necessary to constitute the crime was knowingly done, and the crime was therefore "knowingly committed." The accused in his testimony admitted knowledge of the seriousness of typhoid fever; admitted that his child was seriously ill; and did not deny that the physician offered treatment and nurses free of expense; yet he refused to permit the child to receive the care and attention offered, and which it clearly needed. He was advised by the county health officer that he was laying himself liable to prosecution; yet he persisted in refusing aid for the child. A case of more wanton neglect could hardly be found. There was neither ignorance of fact nor ignorance of law in this case.

In this case the constitutionality of the statute involved was not raised. The authorities cited, however, clearly established the validity and wisdom of the law. The court concludes that the instruction of the trial court, advising the jury that religious belief constitutes no defense under the statute, was correct.

The question of the necessity of medical attendance would be a question of fact for the jury. That question was submitted to the jury, and they found against the accused, and properly so under the record. Under the law in this state, there is probably no way of reaching an adult who refuses to accept medical aid for himself on his own responsibility; but under the statute quoted, persons will not be permitted to allow innocent children, dependent on them, to suffer for the lack of necessary food, clothing, shelter or medical attendance. And the law contemplates the administering of such aid for the protection of the health, as well as the life, of the child.

Liability of Oral Promisor of Payment for Services for Another

(May vs. Roberts (Okla.), 115 Pac. R. 771)

The Supreme Court of Oklahoma says that the defendant said to the plaintiff, a physician, "I want you to go to that little house [pointing same out]; my tenant's wife, Mrs. B., is sick there, and I want you to look after her and take care of her." The plaintiff asked him about the pay, and he said, "I will see that it is paid." It was in answer to the plaintiff's question about pay for such service as he might render to Mrs. B. that he said, "I will see that it is paid." It was error to exclude this evidence from the jury. The evidence was competent and material for the consideration of the jury, in connection with all the facts and circumstances proved, to determine whether the liability created was primary or collateral. The question was whether, under all the evidence, the credit was given solely to the defendant, or to the husband of the woman who was to be treated by the plaintiff, with the understanding that, if the husband did not pay the charge, then the defendant would. If the former, that is, if the defendant's liability was primary, such verbal contract was valid, and the defendant was liable. But if the intention was that the husband of Mrs. B. should be primarily liable, and that the defendant's liability should be only collateral (that is, to answer in case of the husband's default) then the contract was void as within the statute of frauds, which requires promises to answer for the debts of others to be in writing. There might also be a question as to whether there was not a joint liability, that is, whether the husband of Mrs. B. and the defendant were not jointly to be liable.

Liability for Death from Delirium Tremens Precipitated by Injury

(McCahill vs. New York Transportation Co. (N. Y.), 94 N. E. R. 616)

The Court of Appeals of New York affirms a judgment holding the transportation company liable for the death of a man who died from delirium tremens on the second day after being struck by one of the defendant's taxicabs and being thrown about 20 feet, having his thigh broken and his knee injured. He was removed to a hospital and a physician testified that when he was brought there he was unconscious, or irrational rather than unconscious, rapidly developed delirium tremens, and it could be said with reasonable certainty that the injury precipitated his attack of delirium tremens. Of course, it was undisputed, the court says, that the injuries could not have led to delirium tremens except for the preexisting alcoholic condition of the man, and under these circumstances the debatable question in the case was whether the company's negligence was, legally speaking, the proximate cause of his death. The court holds that it was.

The real proposition, however, urged by the company was that it should not be held liable for the results which followed its negligence, either, first, because those results would not have occurred if the man had been in a normal condition; or, secondly, because his alcoholism might have caused delirium tremens and death at a later date even though the company had not injured him. But that proposition could not be maintained in either of its branches, which were somewhat akin.

The principle has become familiar in many phases that a negligent person is responsible for the direct effect of his acts, even if more serious, in the cases of the sick and infirm as well as in those of healthy and robust people, and its application to this case was not made less certain because the facts were somewhat unusual and the injured man's prior disorder of a discreditable character. The principle is also true, although less familiar, that one who has negligently forwarded a diseased condition, and thereby hastened and prematurely caused death, cannot escape responsibility, even though the disease probably would have resulted in death at a later time without his agency. However, it is easily seen that the probability of later death from existing causes for which a defendant is not responsible may be an important element in fixing damages in such a case, but it is not a defense.

Society Proceedings

COMING MEETINGS

American Public Health Association, Havana, Cuba, Dec. 4-9.
Southern Medical Association, Hattiesburg, Miss., Nov. 14-16.
Southern Surg. and Gynecol. Assn., Washington, D. C., Dec. 12-14.
Western Surg. and Gynecol. Assn., Kansas City, Mo., Dec. 18-19.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION

Thirty-Seventh Annual Meeting, held at Nashville, Tenn., Oct. 17-19, 1911

The President, DR. ROBERT H. BABCOCK, Chicago, in the Chair

Addresses of welcome were delivered on behalf of the local profession by Dr. George H. Price, Nashville, and, on behalf of the citizens of Nashville, by Mr. W. R. Cole. These were responded to on behalf of the association by Dr. Albert E. Sterne, Indianapolis.

The following officers were elected: president, Dr. Louis Frank, Louisville, Ky.; vice-presidents, Drs. Albert E. Sterne, Indianapolis, and F. William Werner, Joliet, Ill.; secretary, Dr. Henry Enos Tuley, Louisville, Ky. (reelected), and treasurer, Dr. Samuel C. Stanton, Chicago (reelected).

Pellagra: Its Epidemiology

DR. R. M. GRIMM, of the Marine-Hospital Service said: An investigation was made during August, 1911, in the counties of Whitley, Knox and Bell, Kentucky. The total number of cases was 140. Only sixteen were living in the homes at which they resided at the time when they noticed the first symptoms of the disease. With one exception, the families of the sixteen pellagrins gave a history of using surface or spring water. No observations were made which would lead one to suspect that the disease is hereditary. So far as I was able to determine, corn products in one form or another had been used exclusively by all of the pellagrins. The cornmeal used by the families of the miners in this region is obtained almost exclusively from the stores of the coal mining companies. The cornmeal was not of the best quality.

The Prevention and Eradication of Bubonic Plague

DR. W. C. RUCKER, San Francisco: Plague is primarily a disease of rodents and secondarily and accidentally a disease of man. Man's safety from the disease lies in the exclusion of the rodent and his parasites. This is the basis of all preventive and eradicative work. If man can live in rodent-free surroundings he need have no fear of plague, because if there are no rodents there can be no rodent parasites, and for all practical purposes the flea may be considered as the common vector of the disease from rodent to rodent and from rodent to man. The eradication of bubonic plague, therefore, means the eradication of rodents.

In the city the fight is directed against the rat and its parasites and aims to prevent the spread of the disease from them to man. In the country two measures follow the same general lines as in the city and are modified only to meet the existing conditions, such as the species of the rodent to be combated, the density of the population, and the different character of the buildings. The work of prevention is directed against the rodent and its parasites lest they import and nourish the seeds of pestilence, later to distribute them to mankind.

Preventive Vaccination Against Typhoid Fever

Dr. W. S. Harpole, Chicago: Vaccination has been done in many hospitals and asylums, where nurses, patients, doctors have been protected. Notable are the experiences of Richardson and Spooner in the Massachusetts General Hospital. From 1902 to 1906, twenty-six nurses contracted typhoid fever, and for each case of typhoid fever treated a nurse contracted the disease. In 1909 and 1910, under vaccination, no cases of typhoid occurred among the nurses. The experiences of our army and of hospitals and asylums are sufficiently convincing of the value of this vaccination. Typhoid vaccination is done by the injection of killed cultures of the typhoid bacillus. The germs are usually killed by heat. All persons who are in contact with typhoid cases, as physicians, nurses, hospital attendants and laboratory workers, should be vaccinated. Children and young people going to the country for the summer should be protected.

Typhoid Vaccines in the Chronic Infection

Dr. Willard J. Stone, Toledo, O.: Not only should individuals who are typhoid-carriers receive appropriate vaccine treatment, but all individuals including physicians and nurses, whose duties require the attendance and care of typhoid cases should receive immunizing treatment. By this procedure, many individuals otherwise destined to become chronic carriers might secure protection which would prevent in themselves the possibility of cholecystitis or other late manifestations as well as avoid the possibility of becoming a source of danger to others. Such treatment has been found efficient and productive of little discomfort. Nurses, orderlies and physicians should be regularly immunized at intervals of two or three years as should all others exposed to endemic or epidemic outbreaks. When typhoid bacilli have produced clinical or bacteriological evidences of cholecystitis, it is doubtful whether vaccine treatment will of itself be of avail, surgical drainage of the viscus then being indicated. On the other hand, appropriate vaccine treatment in individuals showing evidences of intestinal or urinary tract perpetuation of the bacilli, without cholecystitis, during convalescence from disease or subsequently, should be given the opportunity of vaccine treatment. Not all will be cured, but the bacilli will disappear in some instances. Chronic carriers, who have been treated by vaccines, should be under the control of the local board of health and furnished employment, if necessary, which would not require the handling of food products.

Diseases Produced by the Colon Bacillus; Diagnosis and Treatment

Dr. Fenton B. Turck, Chicago: The etiology of diseases does not sufficiently interest the American physicians and surgeons, hence our remedial measures are directed to the treatment of symptoms, and frequently we find the surgeon content with the removal of gall-stones, appendices and ulcers, etc., without sufficient interest in the causes of these complaints. Consequently we find many discouraging reports of the end-results of many of these abdominal operations.

Not only surgical diseases but many medical diseases masquerading under various names are now recognized as colon bacillus diseases. Thus Trautner experiments with colon bacillus in rheumatism, Metchnikoff in arterial sclerosis, Opie in hepatic cirrhosis. Migraine and neurasthenic conditions are often associated with increased indican which is chiefly the result of activity of bacillus coli in the intestine. Aside from the usual methods, the diagnosis rests on obtaining active cultures of *Bacillus coli* from the cecum (first clearing the lower bowel and allowing the tube to remain in the bowel until the contents from the cecum and also the ileum pass into a culture tube). A pure culture injected intraperitoneally into a rat indicates the virulence of the *Bacillus coli* used by death of the rat or mouse in a few hours. A test vaccine is used to determine the degree reaction of the patient when injected subcutaneously into the patient.

The treatment is directed first to the reduction of the virulency of the colon bacillus in the intestines by dietetic measures and the restoration of the functions of the stomach and intestines, especially the motor functions, and second to the increase of the means of defense by increasing the antibodies in the blood and tissues of the patient. Autogenous vaccines are introduced subcutaneously, intravenously, by mouth, colon or into the bladder or pelvis of the kidney as the case may require. This combined method has been beneficial in patients who have failed to obtain relief after operation for ulcer of stomach and duodenum, for gall-bladder disease, for removal of appendix, etc. It is over three years since this combined method of treatment was first used, and it seems to prove that the cures are permanent where the treatment is completely carried out.

(To be continued)

MEDICAL SOCIETY OF PENNSYLVANIA

Sixty-First Annual Meeting, held at Harrisburg, Sept. 25-28, 1911

(Continued from page 1390)

Lodge Practice

Dr. Horace M. Alleman, Hanover: Have we any economic conditions justifying lodge practice? The difference between legitimate contract practice and lodge practice should always be remembered in discussing this subject. The effect on the physician so engaged is detrimental to good work and is a hindrance to his advancement in his profession. The membership in these lodges is increased by openly advertising free medical treatment. Thus, the profession is used for a twofold purpose.

DISCUSSION

Dr. George E. Holtzapple, York: The question is how to check this pernicious practice. I believe that it will resolve itself into a personal effort on the part of every physician to help create a proper sentiment against this evil.

Dr. Charles J. Cummings, Williamsport: The state society ought to have a constitutional provision that no county society shall be a component part of it unless said county society bars lodge practice. Then we shall be getting at the thing in a common-sense way.

Dr. Israel Cleaver, Reading: As a cure, I would suggest that the lodges put the money paid by their members for this purpose into a fund from which to pay any physician the member may choose to employ his regular fee.

Dr. Sterling D. Shimer, Easton: In our county society, we finally adopted the rule that no member should accept any contract work for less than the regular fee. My contract work is paid in this way, but I get nothing extra for night work.

The Value of a Library to a County Medical Society

Dr. James M. Anders, Philadelphia: There are great advantages in having an independent medical library in each county society, as the working library is an important factor in medical progress. Reference books and medical periodicals are indispensable to the young physician as a source of knowledge and inspiration. The responsibility for establishing such libraries devolves on the members of the county societies. A special committee, cooperating with the secretary of the county society, who should also be the librarian, could raise a fund for this purpose with the aid of a small assessment. A small amount of this money should be appropriated to the purchase of books to keep the library up to date. Experience proves that not less than three-quarters of the books in large medical libraries are donated. In every county a suitable room could be found, as the result of patient effort. The present methods of transportation make it possible for the members to reach some central place easily, especially if the library is made the meeting-place of the society, so that books and periodicals could be taken out and returned at the time of the meeting.

DISCUSSION

DR. THOMAS A. JAMES, Ashley: The Luzerne County Society started with a very small library, and now has over 6,000 volumes. Every member has a key, and can use the library at any time for reading. Most of the volumes have come by donation, and the duplicates we have traded with other societies. We pay $10 a year dues.

DR. JAMES TYSON, Philadelphia: The journals should be allowed to circulate from one member to another, without requiring a man to go several miles to a center and return them. They could be sent by mail.

DR. JOHN B. CARRELL, Hatboro: In a county such as ours, which is 40 miles long and 20 miles broad, how would members so remote from this library have access to it? I would suggest having a library section of the society, and having each man who wished to belong to it contribute a certain amount of money.

Municipal Milk-Supply

DR. ERNEST J. LEDERLE, New York: We have come to believe in New York City that the only way to guarantee the safety of the milk-supply is to require pasteurization of all but certain grades of high-priced milk. We have adopted a plan for the official grading of milk into three classes: milk for infants; milk for adults, and milk for cooking and manufacturing. Milk used for the latter purposes does not require painstaking inspection, but it must be pasteurized, because one cannot be sure that it will be put to these uses.

Milk and Its Relation to Public Health

DR. PERCIVAL J. EATON, Pittsburgh: Clean, raw milk is recognized to be better as a food than either sterilized or pasteurized milk. Raw, clean milk, modified to suit the individual infant, is the best of the substitute foods. Because of the possibility of infection of man by the bovine tubercle bacillus, tuberculosis among cattle should be eradicated. On account of its known rôle as a disease-carrier, the production of all milk should be constantly watched by competent inspectors. The great value of milk depots is their relation to the morbidity and mortality of infants and young children. I would make a plea for the more general recognition of the economic rights of the producer, and for the education of the masses to the belief that a good product deserves and should obtain a good price, and that the best is none too good for the children.

DISCUSSION

DR. JOHN B. CARRELL, Hatboro: It might as well be understood by the residents of cities that the price of such milk as is desirable, not only for infants but also for adults, must be advanced. It is an impossibility for the farmer to produce with profit the kind of milk that should be used, unless the distributor and his profit are done away with.

DR. JAMES M. ANDERS, Philadelphia: I do not believe that we shall have a good milk-supply until a prolonged campaign of education is carried on among the farmers and dairymen. There is a method by which milk can be produced with comparative cheapness. By means of the cow-testing associations, the farmer can separate the profitable from the unprofitable cows and get rid of the latter, of which most farmers carry a large percentage. It is of importance for the farmers also to learn the proper time and the best method of cooling the milk, as well as the best manner of straining it.

DR. DAVID P. RETTEW, Coatesville: I believe in raising the price of milk. One cent a quart added to the present price would probably make its production profitable. I doubt whether doing away with the distributor and putting the distribution of the milk-supply in the hands of the municipality would work well in certain cities. There must, however, be better business methods of distribution.

DR. HENRY C. WESTERVELT, Pittsburg: Milk has very materially improved in quality and cleanliness without any tremendous increase in the price. You are paying 8 or 10 cents a quart for milk that is better than what you paid the same price for three or four years ago. The farmer is not using more men but merely making them do their work better. I believe in a campaign of enlightenment but not of the dairymen or middlemen. I enlighten the mothers, and they promptly enlighten the men who furnish the milk for their sick babies. Any mother can send a specimen of the milk furnished to our municipal laboratory and get a report on it without the knowledge of the dealer.

A New Sign in the Diagnosis and Treatment of Ulcer and Carcinoma of the Stomach

DR. EDWIN ZUGSMITH, Pittsburgh: A sign of gastric ulcer and carcinoma, which I believe has not heretofore been described, is an abnormal dulness to percussion in the second interspace extending for a variable distance on both sides the sternum. In observations extending over a period of one year, I have noted the presence of this sign in cases of gastric ulcer and much more positively in cases of gastric cancer. Unless the percussion stroke is very delicate, the sign will not be found, for the dulness will be obscured by lung resonance. On the healing of the ulcer the dulness disappears. I believe that this dulness is directly due to enlargement of the lymph-nodes lying along the sternum.

The Relation of the Streptococcus to Scarlet Fever with Active Immunization by Means of Streptococcic Bacterins

DR. JOHN A. KOLMER, Philadelphia: Among the various organisms considered as the probable cause of scarlet fever streptococci have received the most study and attention, although they are regarded as secondary invaders and responsible for a high proportion of the complications. If streptococcic bacterin prevents scarlet fever, then streptococci bear a much closer relation to that disease than we are willing to admit. Our inoculations, however, with the heat-killed streptococcic bacterin did not prevent scarlet fever. As scarlet fever is probably not due to the streptococcus, that organism being responsible only for the complications, the streptococcus bacterin may prevent a severe attack of scarlet fever by producing an immunity against secondary streptococcus infections.

The Treatment of Cardiac Arhythmia

DR. GEORGE W. NORRIS, Philadelphia: The forms of cardiac arhythmia are: (1) Sinus arhythmia, in which the normal inspiratory pulse acceleration and expiratory retardation become exaggerated. This may be symptomatically abated by atropin, but direct treatment is rarely necessary. Rest, diet, hydrotherapy and massage constitute our chief line of defense. (2) Extrasystolic arhythmia, in which one or more beats are dropped, which usually results from accentuated myocardial excitability, although it may be due to heart-block or diminished excitability. When temporary, it needs no treatment; when persistent, treatment consists in lessening the work required of the heart muscle. (3) Auricular fibrillation. It is this variety which so often goes hand in hand with the broken compensation of old rheumatic valvular lesions. These patients require rest, sleep, attention to diet and exercise. When the compensation is bad, absolute rest with laxatives and restricted dry diet will often produce many beneficial results. It is in auricular fibrillation that digitalis accomplishes its most brilliant results. (4) Heart-block, which is due to a depression of conductivity. For the serious form of heart-block seen in myocardial disease no definite rule can be laid down. In incomplete block, atropin, in liberal doses, often arrests the condition. Digitalis is contra-indicated. If heart-block is complete, digitalis may be beneficial. (5) Pulsus alternans, which is due to depression of contractility, a condition which can be inferred when we find an alternating pulse or a half frequency pulse. As this is an expression of exhausted or degenerated myocardium, little can be expected by any direct treatment. The treatment may be said to be that of myocarditis in general.

Case of Massive Pericardial Effusion

Dr. Thomas W. Kay, Scranton: During the past winter five cases of pericardial effusion have come under my observation. In one case at least 4,000 c.c. of fluid were present. The gravity of the case depends not on the quantity of fluid but on the intrapericardial pressure. Paracentesis pericardii is done easily and gives prompt relief, but is usually not permanent. By it one is never able to draw off all the fluid. Excellent results are claimed as a result of passing a trocar into the pericardium and introducing a rubber catheter through the cannula well below and to the rear of the heart. Thoracotomy with incision and drainage of the pericardial sac has been reported to give good results.

DISCUSSION

Dr. A. Stengel, Philadelphia: There is one feature of this discussion which must appeal to all of us in our everyday work and that is the matter of diagnosis as between the serious and the trivial forms of irregularity of the heart. The treatment of cardiac irregularities is infinitely more unimportant than the diagnosis, because, after all, the trivial forms take care of themselves in the long run and the other forms are serious and will remain serious, even in spite of treatment, though they may be helped. The matter of diagnosis is of importance mainly because a proper recognition of the forms that are unimportant may lead to permission to the patient to follow a mode of life that in the end rids him of the trouble; or, on the contrary, if the physician looks on it as serious and gives a serious prognosis it would lead to hopeless invalidism. One ought to be very careful in making the prognosis in these cases. A good rule is that the more the patient is incommoded by subjective recognition of his cardiac irregularity, the greater is the triviality of his condition. The use of digitalis should be governed strictly by its effects, and we should recognize that in actual cardiac disease it sometimes, even in proper doses, does harm. In very large pericardial effusions, the fluid is mistaken for pleuritic fluid, and the aspiration is made far out in the left side and a fluid is obtained but it is really a pericardial effusion. As to the radical operation for pericardial effusion, I should say that it is desirable to have more evidence before we can unequivocally recommend this form of treatment for pericarditis. I should prefer to stick to the old paracentesis for the present.

MEDICAL ASSOCIATION OF THE SOUTHWEST

Sixth Annual Meeting, held at Oklahoma City, Okla., Oct. 10-11, 1911

The President, Dr. M. L. Perry, Parsons, Kan., in the Chair

Officers Elected

The following officers were elected for the ensuing year: President, Dr. A. L. Blesh, Oklahoma City; vice-presidents, for Arkansas, Dr. T. B. Young, Springdale; for Missouri, Dr. H. S. Crossen, St. Louis; for Texas, Dr. B. N. Freeman, Nevada; for Kansas, Dr. W. S. Lindsay, Topeka; secretary-treasurer, Dr. F. H. Clark, El Reno.

Hot Springs, Ark., was selected as the place for holding the next meeting.

Management of the Nervous Child

Dr. M. L. Perry, Parsons, Kan.: The nervous child is the father of the neurotic and neurasthenic adult, but granting this potentiality, it is also true that proper care during the developmental period will often prevent the occurrence of actual disease at a later date. It is not only the functional nervous conditions whose seed is sown in early life, but many preventable organic affections originate within or develop later on the ground work of nervous instability acquired in infancy or during the first few years. Under the term "nervous child" I include: 1. The precocious child, with its highly organized but poorly balanced nervous mechanism, who is capable of rather extraordinary mental effort along certain lines, but prone to an early breakdown. 2. The quick, alert, restless child, whose whole nervous system appears to be hypersensitive, whose mental faculties are so active that concentration is difficult, and who is largely reflex in type. 3. The shrinking and abnormally timid child, who is weak in nerve-force and therefore easily exhausted. 4. The backward child, who is slowed up mentally either on account of defective organs or special sense, or an inherent defect in correlating sense perceptions and forming ideas. In the care of such children the influence of nutrition and dietetics is of paramount importance. Malnutrition is a potent factor in the development of nervousness as well as in aggravating the condition when it exists. There is a crying need of reform in our educational system. A more thorough inspection of school children should be made, and school authorities should recognize the necessity of special class work in the public schools for defective children not ordinarily classified as feeble-minded.

Pancreatitis: Suggestions as to Etiology and Surgical Treatment

Dr. A. L. Blesh, Oklahoma City: Chronic pancreatitis in association with bile-tract infections is not uncommon. Without this association it is comparatively rare. When present, while it adds more or less to the symptom-complex, the clinical syndrome is so overshadowed by gall-tract infection that it is rarely diagnosed in the absence of a palpable enlargement of the head of the pancreas. Both pancreatic and gall-tract infections may be due to an infection from below, and this, in turn, may depend on a malformed colon, causing a high degree of coprostasis. The frequent association of pancreatic biliary infections, duodenopyloric ulcers, and chronic appendicitis is at least suggestive of a common exciting cause. In this train of sequences the fact that we never encounter an acute but always a chronic type of appendicitis, is of great theoretical and practical importance as, at least, hinting the etiology. Direct biliary and pancreatic drainage, or simple gastrojejunostomy, will not always cure the respective diseases but will always give temporary relief. This fact suggests that respective operations do not always measure up to the pathology and etiology. In properly selected cases, Lane's operation should be added. If done in time, perhaps the latter, in properly selected cases, would be sufficient.

DISCUSSION

Dr. Bacon Saunders, Fort Worth, Tex.: There is one thing that impresses me, namely, the marked tendency to search for something wonderful every time the surgeon opens the abdomen for the relief of some intra-abdominal condition. It would be better not to look for these wonderful things when we operate. I have straightened out many of these kinks by removing the apparent pathologic condition. I have cured many cases of chronic pancreatitis by drainage of the biliary tract. I have had a great many cases in which things looked curious, but after removing well-known pathologic conditions the patients have recovered.

Dr. J. H. Riddell, Enterprise, Kan.: When a surgeon opens the abdomen and finds bands of adhesions, if they have nothing to do with the pathologic condition he is going to correct, they should not be severed. If a surgeon should open my abdomen, I would not want him to remove any section of my anatomy that looks right, for fear it might give me subsequent trouble.

Dr. John F. Binnie, Kansas City, Mo.: We should only remove the real pathologic condition that is causing the trouble; we should not take out an appendix that is not causing trouble.

Dr. Howard Hill, Kansas City, Mo.: I have been having a series of cases of gall-bladder trouble, and in twelve out of thirty or forty cases there has been inflammation of the pancreas, and in most of them the appendix seems to have been affected primarily.

Retrocecal Appendicitis

Dr. J. N. Jackson, Kansas City, Mo.: There are two anatomic positions of the appendix that are extremely unusual, and when the appendix is situated in either of them and is inflamed it gives rise to a different set of symptoms and leads to delay in diagnosis. These are the retroperitoneal and retrocecal types of appendicitis. In the surgical treatment in the retrocecal type, the incision should be made farther out than usual to avoid infection of the peritoneal cavity, possibly splitting the outer fold of the mesocolon so as to turn the colon over to the inside to get at the appendix behind. After removal of the appendix, sometimes there is an abscess cavity to contend with, and the patient is subject to the usual infection following cellulitis. Instead of inserting a drainage-tube, the cavity should be disinfected thoroughly with iodin or phenol (carbolic acid), followed by alcohol and packing. In cases in which an abscess has ceased to be local and has spread behind the intestine and peritoneum, under the colon, a counter-opening should be made to get drainage at the most dependent point.

DISCUSSION

Dr. Bacon Saunders, Fort Worth, Tex.: In these cases of appendicitis the symptoms are so slight that they are frequently overlooked, but the patient does not get well. He develops a septic condition and the surgeon sees him one or two weeks afterward and finds out what the trouble is. In these cases I usually make the incision entirely outside of the colon, and in a large percentage of them it is necessary to resort to posterior drainage. A small drain will not do much good.

Dr. H. C. Crowell, Kansas City, Mo.: I have never seen a case in which the appendix is beneath the peritoneum. One of my patients, a girl of 12, who was subjected to the Ochsner treatment for twelve or fourteen days, had a retrocecal abscess. There was a very much distended space in this region. I cleaned out the abscess thoroughly, but the patient died immediately, and I believe death followed because in opening up and disturbing this abscess so effectually at the time, I liberated an undue number of toxins. I believe we frequently have sudden deaths following large abscesses by disturbing the relations and having absorption of the toxins. Had I opened the abscess in this case in a limited way and drained, I feel certain that the girl would have recovered.

Dr. John G. Sheldon, Kansas City, Mo.: In some of these cases in which the appendix is retroperitoneally located, there may be involvement of the ureters.

Dr. J. D. Walker, Caney, Okla.: A patient had typical symptoms of appendicitis, but when the abdomen was opened no inflammation could be found. In tracing the ascending colon down to its termination and finding its union with the small intestine, I found an organ about the size of a goose quill, which I took to be the appendix. I removed it, and the patient recovered.

Dr. J. M. Inge, Denton, Tex.: It is important in these retroperitoneal conditions to go in back of the peritoneum, but how many surgeons, in making an incision, go far enough back to avoid the peritoneum? In some of these cases it is not good surgery to break up dense adhesions in the effort to find the appendix and remove it.

Postoperative Ileus: Report of Case Relieved by Intestinal Puncture

Dr. Leroy Long, McAlester, Okla.: Following the removal of a cystic tumor on the right side, involving both tube and ovary, with an ectopic gestation in the left tube, the round ligaments were shortened on account of a retrodisplacement, and the appendix was removed. Several hours later intestinal obstruction occurred, which was relieved by puncture.

Chronic Colonic Intoxication

Dr. John F. Binnie, Kansas City, Mo.: Chronic intestinal stasis is exceedingly common; it gives rise to diverse and obscure symptoms, and is at least one cause of neurasthenia. It may be due to various causes, but the real etiology is yet unknown. Failure to obtain relief from symptoms of appendicitis after appendectomy is often due to the fact that appendicitis, if present at all, was merely an accident in the course of a case of chronic intestinal stasis. In every operation for chronic appendicitis, the surgeon ought to examine the whole cecum and the terminal segment of the ileum.

DISCUSSION

Dr. H. C. Crowell, Kansas City, Mo.: Some forms of intestinal stasis are benefited by attention to diet and medication, but a large number of patients suffer from chronic auto-intoxication and neurasthenia on account of adhesions or interference with the peristalsis of the gastro-intestinal tract, and it is the duty of every surgeon who opens the abdomen to make a careful examination in every case to see if there exist adhesions that may interfere with proper peristalsis. In pericolitis I believe that the membrane is congenital, as it does not bear out the conditions, pathologically or histologically, of an inflammatory product.

Dr. A. L. Blesh, Oklahoma City, Okla.: I do not believe we are dealing with a single pathologic condition, but with many. I was called to see a young man who was said to have appendicitis, and in the family at the time there was a case of typhoid. I found he had had several such attacks as he was then suffering from. They consisted in pain, more or less marked, without marked radiating tendencies, in the right iliac region, near McBurney's point. The man's condition at the time was one of profound toxemia. I was fearful that the soreness in the right side was due to a typhoid perforation at the lower end of the ileum. Since there was no danger from waiting, we waited and the condition cleared up. These cases are peculiar in that they do not have a febrile reaction. In other words, they are toxemic.

Abdominal Drainage

Dr. Charles Blickensderfer, Shawnee, Okla.: In the ordinary cases, I prefer the small cigarette drain made by rolling gauze in gutta-percha tissue and thoroughly moistened in normal salt solution. The length is to be governed by the length of the drainage tract to be established. In thick, fat abdominal walls, a short drain of this character extending from the muscular fascia to the surface for a period of twelve hours will prevent mural abscess. Where pus is to be drained, a soft rubber tube of proper caliber may be wrapped with gauze and enveloped in rubber tissue. It is sometimes wise to have a strand of straight gauze lying within the central tube. This can be removed and replaced with others when necessary. In conclusion, the surgeon should not drain if it is possible to avoid doing so. He should not use dry gauze for drainage. He should not tuck or fold back and forth gauze to be used as a drain. Gauze packs are useful to control hemorrhage, but often act as plugs where drainage is sought. One should not use a long drain if a shorter one will suffice. The drain should be removed as soon as its service has been performed, remembering that in pus cases drains are useful for a much longer time than in relatively clean cases.

DISCUSSION

Dr. John F. Binnie, Kansas City, Mo.: Instead of the familiar cigarette drain, it is a good plan to take some strands of ordinary wool, such as used in making thick socks, sterilize it, and use it with a hard rubber tube. It will be found to be better than gauze.

Dr. W. J. Jolly, Oklahoma City: In all wounds, if we have an idea that infection has taken place, the proper thing to do is to drain. I have closed wounds, not having any extra trouble at the time, but have had to reopen them, which is unsatisfactory.

Dr. J. D. Griffith, Kansas City, Mo.: If I want rapid exosmosis, I use sterile petrolatum mixed with normal salt solution. This, being of greater specific gravity than the exudate that is to come out, will produce exosmosis in the capillary attraction. I have been using it for some time and it cuts drainage short and gives me an abundance of drainage. If you put one-quarter sterile petrolatum on the gauze you will find the exudate will be increased very materially.

Septic Infection

Dr. W. J. Jolly, Oklahoma City: In puerperal septicemia we are helpless so far as specific treatment is concerned. The local treatment usually used, curettage, is harmful and only opens up new avenues for the absorption of toxins, and aggravates the condition. While it is the ideal treatment in sapremia caused by a blood-clot or retained placenta, it is to be condemned in true septicemia. Serums, I believe, are worthless. A few patients get well under any treatment, but in my own experience serums do not modify the disease in the least. Our only treatment for the general septicemia is supportive—easily digested, nourishing food, and stimulants to sustain the patient until Nature manufacturers antibactericidal serums or opsonins to destroy the bacteria.

DISCUSSION

Dr. S. M. Mayberry, Enid: I believe in the use of the curet in removing portions of retained placenta, and I think there are times when this instrument, if not properly used, would necessarily carry infection into the healthy muscular coat and do harm. When it comes to washing fresh wounds, after removing all foreign material, I favor the use of tincture of iodin and the application of a hot, moist boracic acid and 95 per cent. alcohol dressing.

Dr. John F. Binnie, Kansas City, Mo.: Many years ago a Berlin surgeon made some investigations as to the sterilization of wounds, and unfortunately in the laboratory found that when bacteria had been in contact with a wound for so many seconds or minutes there was no use in trying to do anything. The bacteria were absorbed according to the laboratory experiments. This would have brought about to a large extent therapeutic nihilism if there had not been found "a nigger in the wood-pile" as regards these experiments. More recently Fredreick, carrying on similar experiments, found that bacteria in a freshly-made wound may be reached by aseptic or antiseptic means for a period of six or seven hours after the wound has been infected. Our methods of treatment of fresh wounds have changed in the last few years.

Do You Do Your Duty in the Obstetric Chamber?

Dr. David A. Myers, Lawton, Okla.: A wholesome surgical fear and a good surgical conscience are two very essential things for a physician. Do not let your surgical fear extend to the point that you will not repair the cervix following childbirth, and do not let your conscience dig you for not doing so. The technic, when once tried, is very simple, and the results are so good that the procedure should occupy the same place as the immediate repair of the perineum.

Cerebrospinal Meningitis

Dr. Wilmer L. Allison, Fort Worth, Tex.: The interesting features in my case were the protracted course after marked improvement following the use of serum; the violent reaction which followed the last four doses of serum, the internal hydrocephalus, the relief of which was followed immediately by marked improvement; the clear mentality throughout the case, and the increased growth of hair over the entire body.

MICHIGAN STATE MEDICAL SOCIETY

Forty-Sixth Annual Meeting, held at Detroit, Sept. 27 and 28, 1911

(Concluded from page 1393)

The Diagnosis of Heart Disease

Dr. G. W. McCaskey, Fort Wayne, Ind.: A complete anamnesis is important in studying a case of suspected heart disease. Inspection is too often cursory. Palpation is much neglected. Preliminary percussion may be made by holding stethoscope over area of superficial dulness and percussing lightly to edge of relative dulness. Findings may then be corroborated by ordinary percussion. The Roentgen ray is of immense value in determining the exact shape and size of the heart and the character of the cardiac movements. The orthodiagraph gives the most scientifically exact outline of the heart. Auscultation is very important, but has held too commanding a position. The significance of murmurs depends on their associated signs and symptoms. The rhythm and character of the sounds are more important *per se*. The study of the venous and radial pulse by synchronous tracings made with polygraph is most important, particularly in the study of arhythmias and heartblock. The electrocardiogram and the cardiophonograph are also of immense importance. The study of blood-pressure is absolutely essential though usually due to extra cardiac conditions. Respiratory embarrassment, hepatic engorgement, and dropsy are the time-honored signs of a failing heart. Hepatic engorgement should be sought for more constantly than it is. Fatal heart disease may occur without any of these signs being obtrusively present or even present at all.

The Heart in the Acute Infections

Dr. C. G. Jennings, Detroit: It is probable that acute degeneration of the myocardium results in every acute general infection attended by fever and other symptoms of toxemia. The extent of this degeneration will depend on the type, the virulence of the duration of the infection. Edema and cellular infiltration may precede, accompany or follow the onset of degeneration of the muscular fibers. In certain prolonged cases, chronic interstitial myocarditis is developed. Heart failure from acute myocardial degeneration and inflammation does not usually come in the early days of acute infection. Time must be given for the degenerative changes to weaken the heart. In diphtheria, however, possibly in pneumonia, myocardial changes advance with great rapidity and by the end of the first week may threaten life. In typhoid, influenza and other prolonged infections, the myocardium does not cause apprehension until the second or third week or later.

Circulatory failure in the first few days of an acute infection is usually due to vasomotor paralysis. In circulatory failure during the second week, vasomotor paralysis is still an important factor, although myocardial changes are usually present. The failing heart in the late stages of an acute infection is the result of myocarditis with or without dilatation. From the onset of the disease it should be the aim of the physician to limit toxemia by the early administration of specifics, as in diphtheria and rheumatism, the maintenance of free elimination, the intelligent use of hydrotherapy and careful attention to dietetics and the hygiene of the sick-room.

DISCUSSION OF PAPERS BY DRS. McCASKEY AND JENNINGS

Dr. A. W. Hewett, Ann Arbor: The particular methods that have been introduced in diagnosis of heart disease, or one of the most important ones, is that of determining the blood-pressure. The form of irregularity in which the heart is extremely irregular has been shown to be due to auriculofibrillation, and the muscle is in a continuous state of fine fibrillation. Digitalis does not raise the blood-pressure in man to any appreciable extent, and this is a very important point, because it is very common for physicians to decline or hesitate to give digitalis to patients with high blood-pressure. If a patient has high blood-pressure, I hesitate to give it; but if he has a low blood-pressure, it is of practical importance, in most cases, to raise it by administering digitalis.

Dr. G. W. McCaskey, Fort Wayne, Ind.: It has been assumed, on ordinary clinical grounds, that digitalis, in ordinary dosage, does not materially raise blood-pressure. I am unconvinced that the tendency of digitalis is not to raise blood-pressure. I have been unconvinced all the time, during recent years, and in those cases particularly where I am afraid of an increased peripheral resistance, I combine vascular dilators to counteract the vasoconstrictor effect which I assume to be present in the use of digitalis.

Acute Anterior Poliomyelitis

Dr. B. F. Green, Hillsdale: In Hillsdale County the epidemic of 1910 began in July and ceased in November, with a total of seventy-two cases, not including any of the abortive type. There were twelve fatal cases, four attributed to polio-encephalitis and eight to paralysis of the respiratory muscles. The spinal type occurred in fifty cases. The ages varied from 2 to 70. Nearly half the patients were under 10 years of age. In only four families were there second cases developing paralysis. In the fatal cases death occurred in the largest number within three days from the onset, though in one case it was delayed until the fourteenth day. So far this year Hillsdale County has had only one case, the patient at present being convalescent.

The General Use of Fat in the Diet

Dr. James E. Davis, Detroit: Indoor life is provocative of an appetite which shows a decided preferment for carbohydrate and protein and a distaste for fat, the result being an unbalanced diet, causing too frequently carbohydrate indigestion and protein errors of metabolism. This indoor class can metabolize fat better than protein, and the difficulties with the digestion of adequate quantities of fat should be met by skilful cooking, which will avoid subjecting it to prolonged high temperatures and will seek suitable combinations with a carbohydrate. Fat in the diet of natural selection is 8.3 per cent. of the total food weight, but it furnishes 16 per cent. of a day's total energy. No other food requires so careful an investigation of individual peculiarities in each patient as fat.

The Relation of Premature Rupture of the Amniotic Sac to Puerperal Sepsis

DR. GEORGE KAMPERMAN. Ann Arbor: A study of 300 recent confinements shows that premature rupture occurred thirty-eight times or in 12 per cent. of all cases. In practically all of these thirty-eight cases the amniotic sac ruptured before the beginning of labor. The labors in these cases of premature rupture were not longer than the average. Among the 262 cases where the membranes ruptured normally. there was a slight rise in temperature in 1.4 per cent. and a severe sepsis in 0.4 per cent. But among the thirty-eight cases where membranes ruptured prematurely, there was a slight rise in temperature in 13 per cent. and severe sepsis in 8 per cent. In this series puerperal sepsis occurred about ten times as often after premature rupture as it did after normal rupture of the membranes. The increased frequency of infection is probably due to the open birth canal. vaginal examinations contaminating the amniotic cavity with the vulval bacteria. As a prophylactic it is suggested that in all cases of premature rupture, the vulva be cleaned and protected from contamination, and that examinations be made per rectum instead of per vaginam.

DISCUSSION

DR. EUGENE BOISE. Grand Rapids: I am glad that statistics have shown that primiparæ are much more likely to sepsis than the multiparæ, but the question is, why is it so? Is it not probable because the vaginal examinations are made more frequently in primiparæ than in multiparæ, and the membranes have ruptured prematurely. The question suggests itself, is it not possible that the rupture of the membranes and the discharge. and the manner in which the fluid is discharged has something to do with it? There is also more apt to be an injury to the cervix in these cases of premature rupture of the membranes.

DR. E. GEORG, Ann Arbor: Unless a sterile bath can be taken, every pregnant woman is liable to infection from the douches, especially if the membranes have ruptured. An important thing in the care of these patients is that they should use a bed-pan, particularly after the membranes have ruptured.

DR. C. E. BOYS, Kalamazoo: It would seem to take a very generous supply of rubber gloves and much boiling and frequently changed hand solutions in order to make rectal examination feasible. After all, one sometimes questions how much good these examinations do, anyway. Personally, I depend more and more on external examinations for diagnosis of position and presentation.

External Pelvimetry with Special Reference to Method of Measuring the Outlet

DR. HOWARD H. CUMMINGS, Ann Arbor: Routine pelvimetry of the outlet has been sadly neglected. The best method of outlet pelvimetry is that taught by Professor Williams of Johns Hopkins. The diameters of the outlet of a normal pelvis should measure, according to Klein, who based his conclusions on the study of 113 normal pelves as follows: Transverse, 11 cm.; anterior sagittal, 6 cm.; posterior sagittal 9.5 cm.; anteroposterior, 11.5 cm. Williams measured 185 normal pelves and obtained as average outlet measurements the following: Transverse, 10.5 cm.; anterior sagital, 5 cm.; posterior sagittal, 7.5 cm.; anteroposterior, 11.5 cm. A series of seventy cases measured at the University of Michigan Maternity Ward gave the following average outlet measurements: Transverse, 10.2 cm.; anterior sagittal, 5.4 cm.; posterior sagital, 8.5 cm.; anteroposterior. 11.3 cm. Funnel pelvis was found in four cases in ninety consecutive obstetric patients.

Coloptotic Constipation

DR. L. J. HIRSCHMAN, Detroit: All cases of coloptosis must have associated with them an atonic condition of the colonic musculature, as all coloptotic patients are not constipated neither have all constipated patients coloptosis. In many patients who are coloptotic, a compensatory muscular development of the colon overcomes the ptosis. The surgical treatment consists of mesenteric suspension of the ptotic bowel, rotation and anchoring of prolapsed cecum and lateral anastomoses of parallel dependent limbs of prolapsed transverse and descending colon. Hygienic, dietetic and physical therapeutic measures are advocated in conjunction and following the surgical procedures.

DISCUSSION

DR. P. M. HICKEY: From the fact that about every fifth individual is born with a ptosis, our treatment should begin very early. The schools should take up the matter of correct position. Pupils should not be allowed to go around with the shoulder blades prominent and shoulders bent forward and the abdomen totally limp, but they should be taught the military exercises, and setting-up drill to bring them up in shape and accentuate the development of the abdominal muscles, and then this condition would not be present in later life, and there would not be so many neurasthenics.

Blood-Pressure in Eclampsia

DR. WALTER E. WELZ, Detroit: There is always an increase of intravascular pressure in pregnant women before the advent of eclampsia. The blood-pressure is highest during the convulsive state, and gradually drops to normal with recovery. All women passing through the later months of pregnancy may be placed in one of five groups: (1) normal, (2) eclamptic, (3) chronic nephritic, (4) non-toxic renal, (5) mechanical albuminuria. Blood-pressure readings and urinary analyses are the principal factors of this classification, which should lead to earlier diagnosis, efficient prophylaxis and more definite prognosis in cases of toxemia of late pregnancy. Abnormal urinary findings are of value only when qualified by blood-pressure readings. The blood-pressure alone is worth more as a diagnostic aid than any other symptom, and for this reason should be made use of as the indicator for the care of threatened eclampsia. If the high pressure of late pregnancy is controlled, the patient may pass through pregnancy, labor and puerperium without the advent of convulsions. Veratrum viride apparently helps control the convulsions by slightly lowering blood-pressure, which causes a subsidence of the serious condition in acute eclampsia.

2. **Pernicious Anemia.**—Reasoning by analogy as well as on the basis of clinical observation, Moffitt appears to incline to the belief of an infectious origin of this disease.

3. **Coagulation Time of Blood in Various Diseases.**—Secondary anemias, other than those due directly to hemorrhage, appeared to have a normal clotting time. Twelve observations were made by Rudolf and Cole on six patients, with an average clotting time of 7.8 minutes, and a range of from 10.5 to 6.4 minutes. When the anemia resulted from hemorrhage, the clotting time was invariably shortened, except in the case of hemophilia, when hemorrhage appeared to have no such effect. In eight cases of hemorrhage, with fourteen observations, the average clotting time was 6.6 minutes, with a range of from 5.2 to 10 minutes. The one that showed a time of ten minutes was a case of epistaxis in an old woman. It was not severe, but was very persistent and hard to control. There was no history in the family of bleeding nor of previous hemorrhages. In one case of severe traumatic hemorrhage the clotting time was 6.4 minutes. The patient was transfused by Crile's direct method, and afterward the clotting time was practically the same (6.5 minutes). The donor, his brother, showed before the transfusion a clotting time of 8.5 minutes, and directly after, one of 5.8 minutes. Six healthy children were tested before and after the administration of a prophylactic dose of antitoxin. The dose given was always 500 units, which bulks about 3 c.c. There was no change produced in the clotting time.

Two cases of hemophilia, both typical as regards the family tendency to hemorrhage, etc., showed very different readings as regards their time of coagulation, one giving an average of 9.5 minutes and the other one of nineteen minutes. The one that showed the greater delay was given calcium lactate freely for two days, 30 grains every four hours, with a sequence of a clotting time of twenty minutes. A few days later he was given 15 c.c. of rabbit blood-serum subcutaneously without any perceptible effect on the clotting time. Six cases of jaundice showed an average clotting time of 9.6 minutes as a result of ten observations. In none of them had there been any recent hemorrhage. A case of splenomyelogenous leukemia, which remarkably improved as regards the blood-picture under the biweekly use of Roentgen rays showed some lengthening in clotting times as the leukocytes dropped in number. Forty-seven observations were made on seventeen cases of lobar pneumonia, and the average clotting time was 8.1 minutes, but ranged from 5.5 to 12.75 minutes. The clotting time did not vary with the acuteness of the infection, two fatal cases showing a time of 8.25 and 8.75, respectively, shortly before death. No marked daily variations occurred. Three cases of purpura, in which subcutaneous hemorrhages occurred without definite cause, showed an average coagulation time of 6.16 minutes from eight observations, the range being from 4.9 to 7 minutes.

Thirty-eight observations were made on the blood of fifteen patients with acute rheumatism, and the average clotting time was found to be 10.2 minutes, with a range of from 7 to 14.3 minutes. Thus, the clotting time in acute rheumatism seems to be lengthened. It was noted that the clotting was delayed as long as the acute pain lasted, but it did not seem to have any special relation to the degree of fever present. All of these patients were freely treated with salicylates, but the delay in the clotting time was not due to this medication, as in several of the cases the first estimates were made before the remedy was commenced, and in most of them the drug was still being given after the pains had ceased and the coagulation time had consequently become faster. Sixty observations were made on twenty-six cases of typhoid, and the average clotting time was found to be 7.1 minutes, with a range of from five to twelve minutes. The severity of the invasion did not seem to have any effect on the clotting time.

9. **Sound Production and Sound Conduction Along Respiratory Tract.**—Barach found that the "bronchial breathing" heard at the acromial end of the clavicle has its origin at the manubrium sterni, which receives sound vibrations from the trachea behind. The cavernous breathing heard over the cranial bones, particularly the occipital, has its source of origin in the nasal fossa which acts as a resonator. In the nasal fossa, the nasal resonator, a definite amount of sound is produced, and this sound added to the sound wave created along the lower portions of the respiratory tract, makes up the "sound total," which is heard when auscultating. That the nasal resonator is an active factor in auscultatory sound production is readily appreciated by observing the weakening of the respiratory sounds which occur when its action is eliminated. From this it is evident that auscultatory sound production does not begin at the larynx. This, too, shows that the examiner must take into careful consideration the condition of the nasal resonator, and whether the mouth is opened or closed, in the proper interpretation of his auscultatory findings. The observations on tracheotomy cases throw light on the part played by the larynx, which seems to be of less importance than is generally believed. They show that elimination of the larynx results in modification of the pitch and volume of the bronchial and vesicular sounds, but the essential characteristics of these sounds remain unchanged.

36. **Sepsis and Antisepsis in Medicine.**—It is urged by Thayer as an antiseptic prophylactic measure that there should be special typhoid wards, special tuberculosis wards and special isolating wards in which diseases such as bacterial dysentery may be cared for. Precautions such as those now supposed to be taken in connection with typhoid should be taken in the care of patients with diseases such as pneumonia or influenza. Orderlies and nurses with bad colds or tonsillitis should not be allowed to attend regularly to susceptible individuals or to those in whom the contraction of the malady might produce grave results, such, for instance, as patients suffering with mitral disease. Every hospital ward should be thoroughly and effectively netted against flies and mosquitoes. The omission of a precaution so elementary in its necessity as this, should be regarded as criminal negligence. Not only nurses and orderlies, but attending physicians, should wear clean uniforms or gowns, whenever attending wards containing contagious diseases and remove them on leaving the wards. And among contagious diseases, Thayer includes such maladies as typhoid, tuberculosis and

can metabolize fat better than protein, and the difficulties with the digestion of adequate quantities of fat should be met by skilful cooking, which will avoid subjecting it to prolonged high temperatures and will seek suitable combinations with a carbohydrate. Fat in the diet of natural selection is 8.3 per cent. of the total food weight, but it furnishes 16 per cent. of a day's total energy. No other food requires so careful an investigation of individual peculiarities in each patient as fat.

The Relation of Premature Rupture of the Amniotic Sac to Puerperal Sepsis

Dr. George Kamperman, Ann Arbor: A study of 300 recent confinements shows that premature rupture occurred thirty-eight times or in 12 per cent. of all cases. In practically all of these thirty-eight cases the amniotic sac ruptured before the beginning of labor. The labors in these cases of premature rupture were not longer than the average. Among the 262 cases where the membranes ruptured normally, there was a slight rise in temperature in 1.4 per cent. and a severe sepsis in 0.4 per cent. But among the thirty-eight cases where membranes ruptured prematurely, there was a slight rise in temperature in 13 per cent. and severe sepsis in 8 per cent. In this series puerperal sepsis occurred about ten times as often after premature rupture as it did after normal rupture of the membranes. The increased frequency of infection is probably due to the open birth canal, vaginal examinations contaminating the amniotic cavity with the vulval bacteria. As a prophylactic it is suggested that in all cases of premature rupture, the vulva be cleaned and protected from contamination, and that examinations be made per rectum instead of per vaginam.

DISCUSSION

Dr. Eugene Boise, Grand Rapids: I am glad that statistics have shown that primiparæ are much more likely to sepsis than the multiparæ, but the question is, why is it so? Is it not probable because the vaginal examinations are made more frequently in primiparæ than in multiparæ, and the membranes have ruptured prematurely. The question suggests itself, is it not possible that the rupture of the membranes and the discharge, and the manner in which the fluid is discharged has something to do with it? There is also more apt to be an injury to the cervix in these cases of premature rupture of the membranes.

Dr. E. Georg, Ann Arbor: Unless a sterile bath can be taken, every pregnant woman is liable to infection from the douches, especially if the membranes have ruptured. An important thing in the care of these patients is that they should use a bed-pan, particularly after the membranes have ruptured.

Dr. C. E. Boys, Kalamazoo: It would seem to take a very generous supply of rubber gloves and much boiling and frequently changed hand solutions in order to make rectal examination feasible. After all, one sometimes questions how much good these examinations do, anyway. Personally, I depend more and more on external examinations for diagnosis of position and presentation.

External Pelvimetry with Special Reference to Method of Measuring the Outlet

Dr. Howard H. Cummings, Ann Arbor: Routine pelvimetry of the outlet has been sadly neglected. The best method of outlet pelvimetry is that taught by Professor Williams of Johns Hopkins. The diameters of the outlet of a normal pelvis should measure, according to Klein, who based his conclusions on the study of 113 normal pelves as follows: Transverse, 11 cm.; anterior sagittal, 6 cm.; posterior sagittal 9.5 cm.; anteroposterior, 11.5 cm. Williams measured 185 normal pelves and obtained as average outlet measurements the following: Transverse, 10.5 cm.; anterior sagital, 5 cm.: posterior sagittal, 7.5 cm.; anteroposterior, 11.5 cm. A series of seventy cases measured at the University of Michigan Maternity Ward gave the following average outlet measurements: Transverse, 10.2 cm.; anterior sagittal, 5.4 cm.; posterior sagital. 8.5 cm.; anteroposterior. 11.3 cm. Funnel pelvis was found in four cases in ninety consecutive obstetric patients.

Coloptotic Constipation

Dr. L. J. Hirschman, Detroit: All cases of coloptosis must have associated with them an atonic condition of the colonic musculature, as all coloptotic patients are not constipated neither have all constipated patients coloptosis. In many patients who are coloptotic, a compensatory muscular development of the colon overcomes the ptosis. The surgical treatment consists of mesenteric suspension of the ptotic bowel, rotation and anchoring of prolapsed cecum and lateral anastomoses of parallel dependent limbs of prolapsed transverse and descending colon. Hygienic, dietetic and physical therapeutic measures are advocated in conjunction and following the surgical procedures.

DISCUSSION

Dr. P. M. Hickey: From the fact that about every fifth individual is born with a ptosis, our treatment should begin very early. The schools should take up the matter of correct position. 36 *Observations on Sepsis and Antisepsis in Medicine. W. S. Thayer, Baltimore, Md.
37 *Rubber Gloves in Obstetric Practice. W. B. Gossett, Louisville.
38 Circumcision and Uncircumcision. R. B. Gilbert, Louisville.

24. Abstracted in The Journal, Oct. 8, 1910, p. 1308.

36. **Sepsis and Antisepsis in Medicine.**—It is urged by Thayer as an antiseptic prophylactic measure that there should be special typhoid wards, special tuberculosis wards and special isolating wards in which diseases such as bacterial dysentery may be cared for. Precautions such as those now supposed to be taken in connection with typhoid should be taken in the care of patients with diseases such as pneumonia or influenza. Orderlies and nurses with bad colds or tonsillitis should not be allowed to attend regularly to susceptible individuals or to those in whom the contraction of the malady might produce grave results, such, for instance, as patients suffering with mitral disease. Every hospital ward should be thoroughly and effectively netted against flies and mosquitoes. The omission of a precaution so elementary in its necessity as this, should be regarded as criminal negligence. Not only nurses and orderlies, but attending physicians, should wear clean uniforms or gowns, whenever attending wards containing contagious diseases and remove them on leaving the wards. And among contagious diseases, Thayer includes such maladies as typhoid, tuberculosis and

dysentery. All attendants should invariably and thoroughly wash their hands on leaving a ward or a bed containing a patient suffering from an acute infectious disease. The observance of the necessary precautions of sterilization of the clothes, eating utensils, excreta and bath water of all patients with infectious diseases, should be as rigidly and thoroughly enforced as are the antisepsis rules in the surgical operating room. Cultures should be taken from the urine and feces of all typhoid patients before their discharge from the hospital and, as a rule, no patient should be discharged until his excreta are free from the infectious organism. Similar steps should be taken with regard to dysentery.

Thayer is convinced that if precautions such as these were uniformly adopted in large hospitals, a great step would be taken, not only toward the immediate protection of the population of that institution and of the surrounding community, but toward the education of the medical and lay public at large, for similar precautions should also be taken in connection with patients whom physicians are attending at their homes. In the case of typhoid, for instance, the house should be thoroughly netted. No flies from that patient should infect the food of his neighbors. Furthermore, when possible no one but the attendants should be allowed in the room of the patient. If, however, it is necessary for one member of the family to be present, that individual should adopt all the precautions observed by physician and attendants. The physician should wear a fresh, clean gown whenever he visits the patient. A sufficient supply of these garments should be kept, so that a fresh one may be worn at every visit. The gown should be placed immediately in a tin boiler and boiled after every visit of the physician, so that in most cases, one or two gowns would suffice. The rules for the sterilization of the bath water, excreta, clothes and eating utensils should be carried out in the same manner as in the hospital. Final cultures should be made in the same way. He says that physicians as a body have been content to limit their practice to the treatment of infections after they have occurred, while the surgeon has long since passed beyond this, and has recognized that his most important duty lies in prophylaxis against this infection.

37. **Rubber Gloves in Obstetric Practice.**—Gossett is of the opinion that it is unnecessary for the obstetrician, under normal conditions, to make a habit of using rubber gloves in every case, if he takes the same precautions in cleansing his hands as the surgeon does before performing a major operation. The man who uses gloves must remember that their employment in no way lessens the necessity for thorough cleansing of the hands beforehand. The same precautions must be taken with the hands as if the gloves were not to be used. And just here, Gossett says, will be a great danger because a great many physicians will think that with the use of gloves this precaution is not necessary.

44. **End-to-End Arterial Anastomosis.**—The authors report a successful case of suture of the femoral artery which had been completely severed, though the ends were held together beneath by some strands of uncut adventitia. The surrounding tissues were infiltrated with blood-clot. The vein and nerve were intact. Crile clamps were applied to the artery, the adventitia trimmed away and the ends sewed together by Carrel's method. The clamps were taken off, and then the clamp on the iliac artery was removed. There was some oozing of blood from the anastomosis, which ceased in two minutes under light pressure. Pulsation was readily felt beyond the suture. The abdominal wound was sewed up in layers, the thigh wound by mass sutures. Sterile dressing was applied, stimulation, heaters and blankets. The recovery was rapid and uneventful, despite the weakness of the patient from loss of blood. When seen the next day the left foot was warm and on the day following pulsation of the dorsalis pedis could be readily made out and heaters and blankets were discontinued. The temperature and pulse were normal on the fourth day and remained so. The stitches were removed after the tenth day and on the fourteenth day the patient went home, well except for a small granulating area at the site of the original wound.

45. **Lateral Vascular Anastomosis.**—In the method devised and employed by the authors the artery and vein between which the communication is to be established are carefully dissected out and bull-dog or Crile clamps, rubber-shod, are applied to each vessel at corresponding points. The incision in the artery is made first. A sharp cataract knife, held transverse to the long axis of the vessel, is plunged through the artery in a direction oblique to the horizontal plane in which the vessel lies, so as to form a sector of the lumen with its arc equal to about one-third of the circumference. The knife is thrust in with its cutting edge upward and toward the adjacent vein. The overlying one-third of the artery wall is then divided. At once the retraction of the longitudinal muscle and elastic fibers causes this transverse incision to gape and become an open ovoid. Owing to the fact that the knife was entered obliquely and not perpendicularly, this ovoid looks toward the vein and also somewhat upward. The posterior edge of the opening is thus easily accessible for suturing. As soon as the artery is opened all blood is washed out with salt solution, the adventitia stripped off carefully and the lumen and other surfaces freely bathed with liquid vaselin. The artery is then protected with vaselin-soaked gauze and a similar incision, corresponding in size and position, is made in the vein so that it looks toward the artery and upward. The suture is started by passing the needle through the wall of the artery from without inward, then crossing to the vein and passing here from within outward. When this suture is tied the knot lies outside the vascular lumen. From this starting point a simple continuous suture is carried around the openings in the two vessels, care being taken to avoid purse-stringing. The operation is completed by tying the last suture to the remaining long end of the first tie. No difficulty is experienced in approximating the edges of the incisions and there is no more tension on the thread than in an end-to-end anastomosis.

After completion of the suture, the clamps are removed first from the vein, as in all vascular surgery. If any marked leakage occurs, the weak spots are reinforced by one or two extra sutures. Then the arterial flow is gradually allowed to go over. During the suturing, intima is not always approximated to intima, but with the establishment of the arterial stream through the anastomosis, the "pull" in opposite directions between the two vessels helps to bring about an accurate approximation. This method has been employed with great satisfaction a considerable number of times in animals and was equally simple in execution in the one clinical case in which they have so far had the opportunity to try it. After an interval now of three months, this patient's anastomosis is working splendidly.

56. **How to Get and Keep Competent Health Officers.**—The practice of modern sanitation and hygiene, having for its object the prevention of disease and the prolongation of life, Goler says, does not lead to increased compensation for the health officer, but, cut off from that increase in private practice which devotion to public duty in America always brings, he lands at the end of his career, out of work, out of money and out of health. To the city of his service he has usually given the best that is in him and his labor has been of inestimable value to the life and health of the people of the community; but more than that, if well done, it has been of economic value by lessening the burden which the city has had to bear in caring for the sick, supporting the widowed, the orphaned and the fatherless, in hospitals and other institutions, through private and public charities. Even more than this, the economic value of his work serves to attract attention to the city as a city of the well; and the advantages of a city where health is high and deaths relatively infrequent will be in the time to come, if not now, more than the advertising advantages of bill boards and newspapers. Our cities, says Goler, are beginning to learn the lesson that our insurance companies are learning and just as the insurance men have realized that it is better by care to keep their policy holders alive to pay premiums, than it is to let them die and have the companies pay death claims, so our cities are learning that to grow in population and in importance it is not only necessary to attract new citizens, but it is necessary to take care of the health and lives of those they have.

To do all this, and much more, is the work of the new health officer. To do his work well, he will not only have to exercise all the knowledge he has, but he will have constantly to accumulate new knowledge by frequently attending meetings and conventions of sanitary and social workers. He will also have to do a large amount of research work, both directly and through the labor of those in the laboratory. The equipment of the modern health office, the employment of laboratory workers and the purchase of apparatus, all cost money and in the beginning it may be difficult to get all the money necessary to man and equip the various divisions of the department where advanced work should be going on for the solution and interpretation of questions relating to the public health. For the study of cognate subjects, public spirited citizens equip and endow departments in various institutions and surely no one could place even small sums of money to any better purpose, than for the endowment of special or general work in public health laboratories. Under such conditions, the opportunity to work with a reasonable tenure of office and a fair compensation, the new health officer would become the chief advertiser of the city's health, its wealth and its progress.

75 *Case of Laceration of Trachea. W. L. Wallace and H. O. Brust, Syracuse, N. Y.

75. **Laceration of Trachea.**—While performing athletic stunts this patient fell from a bar, striking the front of his neck across the back of a chair. He was at once in great distress for breath and coughed up much blood. For six days and six nights he was unable to lie down and if he dropped off to sleep for a second, his breath would be instantly shut off. He also had great difficulty in swallowing any food or water. At the operation it was found that three or four of the rings were badly broken from about the third to the fifth or sixth. The proximal and distal ends of the broken trachea were entirely separated and out of line and were held together only by the fibrous membrane which connects the posterior extremities of the cartilaginous hoops. The authors cut away the protruding splinters of the rings and sewed up the tracheal wound with fine chromic catgut. Most of the stitches were passed through the entire wall of the trachea, fastening and holding the broken rings to the sound rings above and below. As the mucous membrane tended to peel away from the rings and plug the breathing space and as the broken rings tended to collapse, they found these through-and-through stitches necessary. After getting the trachial tube air-tight by stitching a piece of fascia over the repair, they were met with another difficulty. When they took off the tenacula, used to hold the ends of the trachea in line and together, the windpipe collapsed, lacking the supporting cartilage hoops. When they pulled forward again, he could breathe. They therefore passed two or three traction linen sutures into the front of the trachea and brought them forward out of the wound, keeping up the tension while the superficial wound was closed and fastened them around the dressing covering the wound. A small rubber drainage tube was left at the lower extremity to take care of the infiltrated tissues. The drainage tube was gradually withdrawn during the next four or five days and at the end of a week the traction stitches were found to be no longer needed. They were therefore removed and the wound allowed to close and he has had no further trouble. One month later, his breathing and speaking were normal.

82. **Muscular Hypertrophy With Weakness.**—Woods calls attention to a disease of the muscular system the characteristics of which are as follows: Increased bulk of affected muscles, which feel firm when contracted; diminished power with early fatigue; hypertrophy of individual fibers, some increase in number of nuclei; no proliferation of fibrous or fatty tissue and no degeneration; tendon-reflexes, mechanical irritability and electrical reactions varied from slight diminution to slight increase. No qualitative electrical changes; a few cases show vasomotor skin changes; and some, dull pain

or tenderness of muscles; the course is slow, but little change occurring from year to year; males are more often affected. The upper extremities were involved more than the lower, though any part of the body may suffer.

85 Comparative Anatomy of Female Genitalia. E. A. Schumann, Philadelphia.
86 Surgical Hints. T. F. Lowe, Washington, D. C.

84. **Posture of Lying-In Patient.**—Mosher's rule is that the woman should be on her feet when she can have a record of two days in which no red color is shown. This puts the average patient up about the fifteenth day. She walks to a chair, is up an hour, increases the limit daily, as she shows her recuperation, judging by the lochia and height of fundus. Mosher examines her the fourth week and cautions her to lie down part of each day through the sixth week. He has had the fundus at the brim by the ninth day and the lochia serosa at the same time and he has had the patient in bed eighteen and twenty days. Usually she may be up half the day the third week and out the fourth week, but Mosher finds a routine practice during the first ten days of raising the head of the bed 8 or 10 inches an advantage in assisting drainage without subjecting the patient to any effort or exertion as is done when on the back rest. Mosher says that American women of the better class are not to be compared in their physical strength with the German peasantry, so that conclusions drawn from hospital statistics of the latter class cannot serve as a criterion for us in putting the patient on her feet. On the other hand, the modern young mother of the present generation who has had an education and an opportunity to live the normal life under direction of her advisor will be found to come through her ordeal in better shape by the adoption of the conservative rule than if she followed the heroic teachings of our brothers across the sea.

As to the change of posture in bed, Mosher's own experience has led him to allow the patient to be turned on her side after the first few hours, this gives her a sense of comfort after the long enforced cramped position on her back with her knees flexed, as she was during labor. He has never been unfortunate enough to see a case of embolism following labor, but appreciates that one is never too old to learn. The catheter is a last resort. The patient is urged to use the pan while lying on her back with various devices of pitcher, douche, water poured from height into a vessel or from a faucet to aid by suggestion the emptying of the bladder. If these expedients fail, she may be turned gently over on her face, lying across the pan to aid by gravity the expulsive effort. Then as a last resort, rather than to catheterize, she is, if the pulse is 90 or under, allowed to be helped out to the jar, which, giving her the upright posture usually accomplishes the desired result. The rule to be laid down from the present state of knowledge, is that the involution of the uterus, the color of the lochia and general condition of the individual patient must govern the conduct of the case, rather than an arbitrary time limit, based on the number of days following delivery.

92 *Effects of Pilocarpin and Atropin on Amylolytic Power and Composition of Saliva. E. M. Ewing, Columbia, Mo.
93 *Actions of Caffein on Mammalian Circulation. T. Sollmann and J. D. Pilcher, Cleveland.
94 Consideration of Some Biologic Tests for Epinephrin. R. G. Hoskins, Columbus, O.

92. **Effects of Pilocarpin and Atropin.**—Ewing found that the volume of the normal saliva, its amylolytic power and the amount and percentage composition of solids secreted, remain approximately constant during a continuous period of secretion of six or eight fifteen-minute periods. If there is any change, it is a very slight falling off of the percentage composition of organic solids and at times of the amylolytic power. Pilocarpin reduces the relative amylolytic power of the normal saliva from 30 to 60 per cent. Although the relative amylolytic power of the saliva is much diminished by pilocarpin, the amount of maltose produced in the total volume of saliva secreted in a given period, after the administration of this drug, is greater than that produced by the amount of normal saliva secreted in the same length of time. "The efficiency" of the secretion is therefore increased by pilocarpin. Pilocarpin increases the amount and tends to increase the percentage of both the organic and inorganic solids of the saliva; the greatest increase is in the organic constituents, however. Any percentage increase of the solids is not nearly so great as the increase in the actual amount secreted. Atropin diminishes the amylolytic power of the saliva from 15 to 30 per cent. Both the amount and percentage composition of total solids secreted are greatly diminished by atropin. The decrease is in the organic constituents. Pilocarpin and atropin affect the factors which influence both the "trophic" and "secretory" elements of the saliva. The effect of pilocarpin and atropin on the secretion, or activity of the ptyalin of the saliva, bears no definite relation to the action of these drugs on the other physicochemical properties of the secretion.

93. **Action of Caffein on Mammalian Circulation.**—The effect of caffein on the circulation is shown by Sollmann and Pilcher to involve the following factors: Cardiac stimulation or depression, according to the dose and rapidity of injection; increased heart-rate, not due to vagus-depression (if the vagus is intact, there may be slowing through central stimulation, but with large doses, the heart escapes from the vagus tone); vasodilation, through peripheral depression of the vasoconstrictor mechanism; central vasoconstrictor stimulation generally ineffectual, also convulsive stimulation; cardiac irregularities, with large doses. The early intravenous injections show the following phenomena: Momentary myocardial depression, succeeded by myocardial stimulation; peripheral vasodilation; central vasomotor stimulation, usually ineffective; increased heart-rate. Blood-pressure: primary fall, followed by recovery and often a small rise. Oncometer: primary fall, followed by larger rise, usually outlasting that of the blood-pressure. Summation of effects with cumulative doses: (a) Total dosage of 20 to 150 mg. per kilo shows: cardiac depression (dilatation); peripheral vasomotor paralysis; moderate and ineffective central vasomotor stimulation; heart-rate reaches maximum and becomes irregular; blood-pressure falls to constant level of 50 to 70 mm.; fall of oncometer. (b) The blood-pressure reaches a constant level when the dosage reaches about 150 mg. per kilo, and further doses of caffein may then be injected with little effect, but sudden cardiac failure may supervene at any time.

95. **Hospital Organization.**—The very complexity of method used in modern medical investigation, Christian says, demands a highly specialized training and continuity of observation for investigators and in addition a large variety of apparatus and trained assistants if advance is to be made. The time element enters to make impossible the application of such methods to more than a relatively few patients at any one period. Consequently the trend of modern clinical investigation is more and more toward the most minute continuous study of a few patients rather than the cursory observation

of the many. Team work and cooperative coordinated observation become increasingly important and hence the necessity of a centralized staff organization. As a result of the influence of present methods of clinical investigation there has come the feeling that for the hospital in which medical investigation is to be conducted, a continuous service with a single head is a more advantageous unit of organization than the older method of broken service with three or four chiefs of coordinate rank on duty during the twelve months. If we examine critically the hospitals of the world with reference to their productivity in investigation, it seems quite certain that productivity is most marked in those that have used the continuous service plan.

How does such a continuous service affect the other functions of a hospital? Is there better teaching with a continuous than with a broken service? Can better men be attracted to the one than to the other? The teaching function of a hospital is, in large part, at least, utilized in connection with a medical school, and staff selections should be made in cooperation with medical schools, thereby securing better men for the work. The continuous service in connection with a teaching position in a medical school is considered more desirable than the broken service, inasmuch as it singles out one man as director and leader and concentrates in him the emoluments of the position. Abler men will naturally seek such a place and selection need not remain local, as was the case with the broken service. The ability to pick the best man wherever he may be is certainly desirable from the pedagogical view point. In fact, it is almost alone in the clinical branches of medicine that the limitations of local selections are tolerated in the choosing of teachers. If in all other branches of educational work the best teachers can be secured by a non-local competition, why not in clinical medicine, surgery, etc.?

107 *Skin Changes in Leukemias and Allied Conditions. H. H. Hazen, Washington, D. C.
108 *Treatment of Malignant Syphilis. H. Morrow, San Francisco.

107. **Skin Changes in Leukemias.**—Observation of three cases and study of case reports in the literature has convinced Hazen that there is a group of cutaneous lymphomata and lymphosarcomata, which includes leukemia and pseudoleukemia cutis, lymphosarcomatosis cutis, lymphodermia perniciosa, mycosis fungoides and the cutaneous lesions of chloroma and myeloma which are closely related. The "serum reaction" recently discovered for mycosis fungoides by Joltrain and Brin and described by de Beurmann and Verdun may prove of service in elucidating the relationship. Lymphodermia perniciosa is a condition closely related to both leukemia cutis and to myocosis fungoides. Mycosis fungoides is an aleukemic lymphomatosis and may become leukemia. The cutaneous lesions of leukemia are probably infiltrations and are comparable with the internal nodules in splenomyelogenous leukemia.

108. **Treatment of Malignant Syphilis.**—Judging from the action of salvarsan on a number of malignant cases of syphilis and on fifty-five milder luetic infections Morrow is of the opinion that salvarsan controls malignant lues quicker and better than mercury. Severe infections seem to clear up as quickly as milder ones. In nasopharyngeal necrosis, the action is quick and sure. If given early in lues, alone or in conjunction with mercury, cases of malignant lues will be a clinical rarity.

115 Exostosis of Os Calcis. J. M. Berry, Albany, N. Y.

114. **Occlusion of Posterior-Inferior Cerebellar Artery.**—Three cases of this very unusual condition are reported by Gordinier. He believes that the branches of the posterior-inferior cerebellar artery which supply the medulla oblongata are physiologic end-arteries and that occlusion of this artery occasions a perfectly definite symptom-complex. The area of softening resultant from occlusion of this artery is strictly limited to the lateral field of the formatio reticularis and restiform body. The salient clinical symptoms of this complex are easily explainable by the loss of functioning of the important tracts of fibers and cranial nerve nuclei contained in the softened area. No motor paralysis is present unless the thrombus extends into the vertebral or basilar arteries. This complex is equally as characteristic as that of the so-called Brown-Séquard's spinal paralysis. The symptoms occasioned by the occlusion of the right posterior-inferior cerebellar artery are exemplified by the three cases narrated. They may be briefly summarized as follows: Sudden onset without disturbance of or loss of consciousness; remarkable and long persistent vertigo with nausea and vomiting; deafness on the right side; absolute inability to swallow due to paralysis of the muscles of deglutition of the right side; voice low and hoarse. Staggering toward the right side, often striking objects on that side, the gait resembling closely that due to cerebellar disease. Complete analgesia and thermic anesthesia of the left side of the arm, trunk and leg and in two of the cases partially so of the left side of the face; absolute preservation of the tactile sense on whole right side; diminution or loss of pain and temperature sense in distribution of the right trigeminal nerve (observed only in case three). Impairment of sense of pain and temperature in pharynx while sense of touch was normal. Contracted pupil, ptosis, narrowing of the palpebral fissure, retraction of eye-ball on right side, loss of sweating on the right side of face and neck. Motor power normal and no permanent paralysis in the domain of the right facial and hypoglossal nerves unless thrombus extends into vertebral. In one case a temporary right-sided facial paralysis existed. Pulse slow in all three cases, probably due to vagus irritation; may be rapid from vagus paralysis. The reflexes were not characteristic. Gordinier believes these symptoms are doubtless due to implication (by the area of softening) and consequent loss of functioning of the following important conducting paths. Cranial nerve nuclei and their root fibers; the ventrolateral ascending tract of Gowers; the direct cerebellar tract of Flechsig; the descending vestibular tract and cochlear nerve roots. Dorsal and ventral auditory nuclei. The cerebello-olivary tract; the nucleus ambiguus or combined motor nucleus of the glossopharyngeal and pneumogastric nerves, vasomotor and sympathetic fibers.

119. **Myocardium in Heart Disease.**—In Warfield's opinion the myocardium plays the chief rôle in disease of the heart. Valvular lesions mean that the heart is working at a disadvantage, its reserve power is not as great, but it does not necessarily mean a weak heart. It means that every case of heart disease, that is, valvular heart disease must be studied carefully as a distinct entity and not as one of a group of cases having similar lesions. It is just here, says Warfield, that there is the important difference between the really good physician and the average doctor. Habits of life, such as eating, sleeping, mental work and worry, defecation, sexual excesses, drinking, and, in short, everything pertaining to the life of the patient, must be most carefully and painstakingly inquired into before we can even begin to tell him what not to do. No detail is too unimportant for study. When we have grasped the fact that there are no unessentials in the history of a person with suspected heart failure, and the fact that a loud murmur does not necessarily mean real heart disease, and the other important fact that the state of the myocardium controls the situation, then we may have hopes of assisting many apparently hopeless invalids to useful lives.

133. **Simple Diet Card.**—The importance of the amount of food as well as kind is emphasized by White. He says that the principles of nutrition are better known than the way to apply them. Our use of foods has been much less accurate than our use of drugs, and dietary mistakes have been common through ignorance of food values or difficulty in estimating them. A large part of the difficulty for the busy doctor has been the amount of work needed to estimate the fuel value of a day's food or the amount of carbohydrate, protein or fat in it. The method of doing this must be simple to be freely used.

He presents a simple diet card used by him. Its object is to avoid weighing of food and tedious calculations by giving food values in household measures. By its use one can readily plan or estimate the value of any simple diet or control the amount of some one food material, such as the carbohydrate in diabetes or the proteid in nephritis. The table gives the following:

1 glass of milk equals 160 calories.
1 glass of ¾ milk and ¼ (4 tablespoons) 20 per cent. cream equals 240 calories.
An eggnog (1 glass milk, 1 egg, 2 teaspoons sugar) equals approximately 300 calories.
A plate of cream soup equals 160 calories.
A glass of skimmed milk or buttermilk equals 80 calories.
An equal amount of gruel equals 75 calories.
A glass of albumin water (white of 1 egg) equals 20 calories.
A cup of beef tea or clear soup equals 5/20 calories.

134. **Phenolsulphonephthalin.**—The authors regard this test as simpler in technic and more accurate in its results than any of the other tests of renal function, although they are in doubt as to the accuracy of the test in chronic nephritis. They believe the test to be of great value in cardiorenal disease in indicating the organ principally or most importantly affected.

1. **Extensive Excision of Colon and Ileum for Tuberculous Disease.**—Barker reports two cases. In one, the hepatic colon was clamped, divided, and its end turned in and sutured. The ileum was cut across over 2 feet from the valve and the whole tuberculous bowel with its mesentery and many infected glands removed from the abdomen as above. Then the end of the ileum was planted into the side of the transverse colon about 2 inches from its closed end. The whole procedure was a most complicated one owing to adhesion, infiltration and glandular infection as well as the difficulty of determining how much of the ileum should be taken, for many small tubercles were scattered widely. The cecum with 4 inches of colon and 27 of ileum were removed. In the second case a lateral anastomosis of ileum to middle of transverse colon was made after the removal of the cecum, ascending colon and hepatic flexure.

3. **Congenital Heart Disease.**—Mrs. B. was one of several daughters of a gouty man who was over 80 when he died. Her mother was also long-lived and appears to have suffered from some variety of chronic arthritis. Mrs. B. married at the age of 17; her husband died some years later from chronic dysentery. One son was the issue of this marriage. He has been healthy and vigorous and still survives at the age of 60, with some slight indication of a gouty proclivity. Mrs. B. married a second time a sufficiently robust man, aged 47 years, and had by him two sons and three daughters, all now living and healthy. Soon after this marriage she became very stout (arthritic obesity). After twelve years this husband died from cardiac dilatation and hemiplegia. Later, at the age of 37 years, Mrs. B. married a third time, the husband being a healthy man about 30 years of age. In this man's family there were signs of gouty proclivity in both parents. (His father died at the age of 79 years from the effects of interstitial nephritis. He had Heberden's nodes, and these also developed in others of his children in later life, with obvious gouty symptoms.) During her pregnancy with her first child by this (third) marriage Mrs. B. suffered from gouty pains in the joints and began to lose a good deal of her obesity. A female child was born at term, somewhat small and weakly, and with a languid circulation. In the course of the second year of its life it was still feeble and backward, although not rachitic, and had a tendency to dyspnea on exertion and progressive clubbing of finger-ends, with duskiness of the lips. An examination of the heart at this time revealed the existence of a murmur in the pulmonary arterial area. The child remained delicate and died from scarlet fever in its thirteenth year. There was no necropsy. Eighteen months later Mrs. B. gave birth to a second daughter. This child was with great difficulty made to breathe on delivery and was cyanotic. It lived only fourteen hours. A necropsy revealed a small opening in the septum ventriculorum and patent ductus arteriosus and extremely small pulmonary veins. The mother had suffered for some weeks during her pregnancy from severe gouty pains in various parts of the body. Two

years later she gave birth to a healthy male child, who is still living and robust and leading an active life.

In the course of the next three years Mrs. B. was found to be the subject of gouty glycosuria, little controlled by dieting. She lost weight very gradually and became feeble. She died at the age of 56 years from pleuro-pneumonia, having suffered from glycosuria in varying degree for twelve years. The husband has since his marriage had several gouty attacks of arthritis, lumbago and phlebitis. The third case of cardiac malformation occurred in the first child born to Mrs. B.'s son by her first husband. This son married a daughter of a distinctly gouty man, who had "regular" arthritic gout at intervals. Their first-born daughter showed obvious signs of congenital heart disease from an early date, suffering from dyspnea, some degree of cyanosis, and backwardness in growth. There was a murmur heard to the right of the sternum and the right ventricle was enlarged. This child hardly grew at all after eight or nine years of age and was very delicate. She died about the age of 13 years. A second daughter was born after this child and has maintained good health. The children by the second husband of Mrs. B. have all grown up in satisfactory health. The eldest and second of the daughters and one of the sons have married and had normal children. The third husband of Mrs. B. married a second time a daughter of an exceedingly gouty father and has had two healthy children by her.

5. **Mediterranean Fever and Fetus in Utero.**—The fetus in the case cited by Samut had been exposed in utero for twenty-one days to the influence of those abnormal conditions of the maternal blood consequent on a severe attack of Mediterranean fever. The child's blood and cerebrospinal fluid yielded a positive reaction to *Micrococcus melitensis* in large dilution. The *M. melitensis* could not be recovered from the internal organs of the fetus. The presence of agglutinins alone in this case raises the important question whether, in the absence of the *M. melitensis* in the fetal organs, they could have been elaborated by the fetal blood, or whether they were transmitted directly from the maternal to the fetal circulation.

8. **Roentgen-Ray Treatment of Sarcoma.**—Harris cites a case of round-celled sarcoma of the right angle of the lower jaw in which colossal doses of Roentgen-rays proved effective.

19. **Ulcerative Colitis.**—The following modes of treatment in Murrell's hands have proved inefficacious or of comparatively little value: (1) Opium and morphin in all forms given by mouth, hypodermically or in enemata, special attention being paid to Dover's powder and compound kino powder. (2) Carbonate of bismuth in large doses up to half an ounce every four hours, alternated with salicylate of bismuth. (3) Astringents including the perchlorid and pernitrate of iron, acetate of lead and sulphate of copper. (4) Intestinal antiseptics, such as *B*-napthol, salol and various preparations of formicaldehyde. High rectal injections of boracic acid Murrell has found useful and in one of his cases (a) the injection of a 1 per cent. aqueous solution of a synthetical preparation of silver at a temperature of 80 F. completely stopped the diarrhea. The peculiarity of the case was that when about five pints had been introduced, the patient being in the knee and elbow position, the fluid was observed running out of the mouth and was identified not only by its physical characters but by chemical tests. Murrell is not in favor of appendicostomy. He says that a right-sided colostomy is in every way preferable and often gives immediate relief to the urgent symptoms. It is a difficult matter to decide when the artificial anus should be closed. If this step is taken at too early a period there may be a return of all the symptoms, while if too long delayed the colostomy may be permanent. Even with a permanent opening, the existence of the patient, especially in the case of a middle-aged man, need not be very uncomfortable and by the observance of simple precautions he is not precluded from the society of his fellow men. Murrell is sure, however, that in most cases it is better to attempt to close the opening at the expiration of about nine months.

47 Wassermann Reaction in Insanity. W. Muirhead.

39. **Malformations of Female Genital Organs.**—The malformations discussed by Giles and cases cited are as follows: 1. Malformations leading to confusion of sex. Case I.—A case of androgyny, the patient living as a married woman. 2. Malformations that preclude or are unfavorable to child-bearing, but allow menstruation and marriage. Case II.—Congenital retroflexion and under-development; hysteropexy; pregnancy. Case III.—Congenital occlusion of the Fallopian tubes.. 3. Malformations that preclude child-bearing and menstruation, but not marriage. Case IV.—Infantile uterus: primary amenorrhea. 4. Malformations that preclude marriage and child-bearing, but not menstruation. Case V.—Stenosis of the vagina, probably acquired. Case VI.—Congenital stenosis of the vaginal orifice. 5. Malformations that preclude menstruation, marriage and child-bearing. Case VII.—Atresia of the vagina; hematocolpos; incision; infection: pyosalpinx. Case VIII.—Atresia of the vagina; absence of menstruation. Case IX.—Absence of vagina; hernia of an infantile uterus in the left inguinal canal. Case X.—Absence of vagina; rudimentary uterus; horseshoe kidney in the pelvis. 6. Malformations that allow of menstruation, marriage and pregnancy, but may be attended by complications. Case XI.—Uterus unicornis; pelvic right kidney; normal pregnancies. Case XII.—Uterus septus with fibromyoma. Case XIII.—Uterus bicornis with ovarian cyst. Case XIV.—Uterus bicornis; exploratory celiotomy. Case XV.—Uterus didelphys.

42. **Possible Toxic Origin of Insanity.**—The following observations are made by Goodall on mental disturbances in autotoxemia. These, amounting to insanity in predisposed persons, occur in various maladies in which the nutrition is

impaired, or in which metabolism and depuration are altered or hindered. Thus, in diseases of the heart, kidneys, liver; in rheumatism, gout or chlorosis; in diabetes. The like disturbances are found with Grave's disease, myxedema, Addison's disease (ductless gland diseases). In the hypothyroidism of myxedema Magnus Levy shows experimentally definite deviation from normal metabolism, removed by administration of thyroid. As the symptoms (including the mental ones) disappear or are greatly mitigated by such means, there is reason for the view that metabolic disorder accounts for the mental disturbances in this disease and if in this, then also, it may be, in other ductless gland diseases. When, however, it comes to administering thyroid or pituitary gland in kinds of insanity in which there is no ground for supposing the action of these glands to be deficient, in order "to promote metabolism," we are empirics, indeed; yet, like empirics, we sometimes do good in this way. Is there any record of the metabolism in these cases before, during and after treatment, asks Goodall.

43. **Multiple Sclerosis.**—Oppenheim regards it as a great advantage for the diagnostician to be familiar with all the different types of multiple sclerosis. But he should never forget that the disease is essentially characterized by the multiplicity of foci. And even when a case appears to be of a pure type it will be his first duty to find out whether some symptom is not present or has not existed that would be the manifestation of foci in some remote part. He only who complies with this exaction will be able to see his way through the vast field of multiple sclerosis.

44. **Head Injury and Nervous and Mental Diseases.**—Mott refers to autopsies in twenty-one cases of general paralysis. The average age at death was 46.5; among these there was not one with a history of head injury. There were 235 male pauper paralytics in whom there was not history of head injury in the notes and the average age at death was 43.5; there were 29 male pauper paralytics with a history of head injury of one kind or another occurring at all periods during the life of the individual; the majority, however, are stated to have occurred within a few months to a few years of the admission of the case to the asylum; the average age at death in these twenty-nine cases was almost the same as in those with no history of head injury, namely, 43.3. In only a very few instances does there seem to be any causal relationship between the injury and the precipitation of the onset, or the acceleration of the course of the disease.

In 1,033 male necropsies there were sixty-one with a history of trauma and of these, twenty-nine were cases of general paralysis (the total number of male paralytic cases was 317), making about 9 per cent. general paralytics in which there is some history of a blow or a fall on the head. Of the 111 female general paralytics, there were only four with a history of trauma, therefore less than 4 per cent. Mott has carefully considered the following points in those cases in which trauma has been the reported cause, or contributory cause, of the paralysis; and the evidence afforded by the notes in the case-books in his judgment does not in a single instance allow one to assume that the head injury was the principal cause of the general paralysis from which the patient died. In some instances the destructive changes in the brain at death, together with the history and clinical symptoms, indicated a duration longer than the period of time between the date of injury and the date of death; in others, and they are not a few, the time elapsing between the date of injury and the onset of symptoms was too long to be accounted responsible as an exciting cause of the disease; in a great number of the cases the nature of the injury, whether severe enough to produce a temporary loss of consciousness or to require medical treatment, is not given, nor is the time and date of the injury mentioned, so that the influence of the injury in the production of the mental disease can never be appraised.

As a general result of his investigations, Mott has come to the conclusion that head injury as an exciting cause was not of much importance either in causing the onset of general paralysis or in accelerating the symptoms. At the same time he has met with a few cases in which undoubtedly head injury may have been the determining cause of the onset of the symptoms and it is not unreasonable to suppose that a syphilitic, if he or she had not received some exciting cause, such as a blow on the head, might never have developed general paralysis, but these cases are rare. General paralysis may not be discovered until an accident or a head injury takes the patient to a hospital or infirmary. There is one essential cause of general paralysis and that is syphilis. All conditions which lead, in a non-syphilitic subject, to neurasthenia may act as exciting and contributory factors; they are sexual excesses, head injuries, alcoholism, speculating, gambling, business worries, leading to prolonged mental excitement and insomnia, in fact, all forms of nervous excitement, singly or combined, which will lead to an exhausted nervous system, especially when acting on an inborn neurotic and erotic temperament in the subject of acquired or inherited syphilis.

Annales de Médecine et Chirurgie Infantiles, Paris

September 1, XV, No. 17, pp. 529-560

48 Simplicity and Ease of Puncturing the Pericardium Through the Epigastrium. (Ponction du péricarde par l'épigastre.) A. B. Marfan.
49 *Typhoid Fever in Infants. C. Achard and C. Flandrin.

51 *Treatment of Malignant Diphtheria. (Traitement des angines diphtériques malignes.) M. Ségard.

49. **Typhoid Fever in Infants.**—Achard and Flandrin declare that the reason why typhoid fever is considered rare in infants is because no one thinks of applying serodiagnostic measures to babes in arms. And yet if this were done many a puzzling febrile affection in infants would be cleared up and the source of epidemics better traced. The typhoid syndrome in an infant simulates an ordinary gastro-intestinal trouble or meningitis or pneumonia. They report a case, the third in their experience. There was no history of typhoid in the environment but two sisters had died recently of supposed measles. The infant was 11 months old, breast-fed, and it recovered after a course of the typhoid of only thirteen days. The symptoms had been general depression and fever, diarrhea one day and then constipation, with vomiting. The lack of symptoms on the part of the lungs, intestines and meninges led to the suspicion of typhoid by exclusion. When the infant left the hospital its dejecta still contained typhoid bacilli. The treatment had been merely fifteen-minute tepid baths at 30 C. (86 F.) and regulation of the diet.

50. **Relapse of Diphtheria.**—A 2-year-old child had apparently recovered from a mild attack of diphtheria when he developed varicella and a suppurative otitis, followed by measles, all within two weeks. Three days after the onset of the measles, severe diphtheria developed. Martin and Darré explain this as due to interruption by the measles of the immunizing process going on in respect to the first attack of diphtheria. The measles sore throat opened up new portals of entry for the diphtheria bacilli still lingering in the throat. They state that the combination of measles and diphtheria has been unusually serious in their experience.

51. **Treatment of Malignant Diphtheria.**—Ségard emphasizes the necessity for intensive serotherapy in these cases and its harmlessness during the three weeks after the first injection, as signs of anaphylaxis do not develop until after this period. In malignant diphtheria the little patient should be watched hour by hour, examining the heart, pulse and urine as well as the throat, and giving antitoxin daily if necessary.

56. **Infant Hygiene and Pathology in the Medical Course.**—Marfan cites statistics to show that the infant mortality in France has declined regularly from 258 per thousand in 1892 to 117 in 1909, and that the mortality during the first few weeks of life is due to congenital debility or syphilis, both of which have to be combated during the pregnancy or before conception. After the first few weeks the mortality is due to digestive disturbances which can best be warded off by breast-feeding under practical supervision. Indifference, poverty and ignorance on the part of parents and midwives are cooperating factors which must be fought. He even hints that the ignorance of infant hygiene on the part of some physicians is not a negligible factor and that the medical schools are responsible for this. He urges that the infant consultations, day nurseries and similar institutions should form part of the daily routine of medical students to train them in the diseases and physiology of young infants which branch of pediatrics is too often neglected in the medical course, and that there should be an examination in infant hygiene and pregnancy before conferring the medical degree. (See Berlin Letter in The Journal, October 14, p. 1299.)

58. **Dialytic Medication.**—Hayem applies this term to dilute aqueous solution of salts, artificial mineral waters, of which he uses five special types, corresponding to the Carlsbad, Vichy and other mineral springs. He has been using them daily for twenty years in his practice with more and more satisfaction for stomach trouble and constipation and for mucomembranous enteritis. He insists that the composition of the solution must be identical each time, the dose and duration of the course carefully defined. The dose should be taken in the morning on the fasting stomach, at a temperature of 104 F. No. 1 is a mixture of 2.5 gm. sodium bicarbonate; 3 gm. sodium sulphate and 1 gm. sodium chlorid to 1 liter of water. The freezing point is 0.255 C. This is indicated in dyspepsia suggesting hyperfunctioning on the part of the secreting glands (hyperpepsia). About 250 gm. is taken in all at twenty-minute intervals, continuing for twenty-five or thirty-five days, no longer, gradually increasing to 500 gm. He cites as contra-indications tuberculosis, heart disease with failing compensation and gastric cancer. He is inclined to ascribe the benefit from this treatment to its action on the liver and pancreas augmenting the receptivity of the duodenum and thus curing the symptoms from the hyperpepsia, notwithstanding that analysis of the stomach content reveals the persistence of the hyperchlorhydria and hyperpepsia, until the vicious circle is entirely broken up. His solution No. 2 contains 5 gm. sodium chlorid and 2 or 3 gm. sodium sulphate to the liter; it is taken fasting in doses of 200 or 250 gm. for four or six weeks as an aid in hypopepsia with a tendency to constipation, especially for patients who have been drugging themselves to excess. No. 3 is the same as No. 2 only that sodium phosphate is used instead of the sulphate. Both are mildly laxative. No. 4 contains sodium chlorid 3 gm. and sodium sulphate 5 gm. to the liter of water. It is useful for sluggish liver and in mucomembranous enteritis in doses of 300 or 400 gm., especially for hyperpepsia with constipation. No. 5 contains 10 gm. sodium sulphate and 5 gm. sodium chlorid to the liter of water. This is a powerful laxative and the daily dose should not be over 250 gm. and not taken for more than a week or two.

60. **Treatment of Congenital Torticollis.**—Ballet and Hitschmann insist on the necessity for wearing a correcting appliance and exercising the muscles after the sternocleidomastoid has been divided. The operation on the muscle is only the preliminary to these measures.

61. **Position Treatment of Gastroduodenal Disturbances.**—Martinet ten years ago called attention to the efficacy of position in treatment of disturbances in the stomach not due to a permanent mechanical obstruction or organic lesion. He has the patient recline on a bed or lounge when he feels discomfort, lying on the right side, the head raised a little, and in this position sip a glass of hot chamomile or linden flower infusion. The pylorus region thus becomes an upright funnel and the upper end of the duodenum slants downward so that the fluids which have passed through the pylorus do not accumulate and stagnate just beyond in what Holzknecht calls the duodenal bulb. Both duodenum and pylorus are soon emptied by the force of gravity.

63 Sporothrix Elbow Arthritis. (Arthrite sporotrichosique.) Sorrel and Verdun.

62. **Ligation of Thyroid Arteries.**—Delore and Alamartine review the experiences in this line at Poncet's clinic at Lyons after a historical sketch of the subject and an illustrated discussion of the anatomy of the thyroid vessels. Experiments on animals seem to show that ligation of one or more of the arteries has no appreciable physiologic effect, but the gland shows histologic changes unmistakably reducing the total of functional capacity. The technic for ligation used by various surgeons and a detailed summary of the work in this line by Berg and Ackermann of Stockholm in fifty-two cases and by Kocher of Berne in fifty-nine cases are compared. Mayo's 225 cases are mentioned but the lack of details, they say, prevent comparison of results. The final conclusions from all these data are that ligation of the thyroid arteries is a logical and safe operation to reduce hyperfunctioning of the thyroid. Mayo's polar ligation of the superior arterial pedicle shuts off both vessels and nerves. When the inferior artery is to be ligated, the best mode of access is back of the sternocleidomastoid muscle. Vascular struma and exophthalmic goiter are the main indications for the ligation; it is contra-indicated in secondary exophthalmic goiter and in exophthalmic goiter of nervous origin. With extremely vascular exophthalmic goiter and in the rapidly progressive toxic forms, ligation of three or four arteries is urgently indicated, even if it is merely preliminary to a radical operation. In mild cases it is well to commence with ligation of the two superior arterial pedicles; if this proves ineffectual, follow with hemithyroidectomy. In cases of moderate severity commence by ligating both arteries of the lobe showing the greatest enlargement; then ligate the superior artery on the opposite side, and, if necessary, follow with a complementary hemithyroidectomy.

66 *Present Status of Arteriovenous Anastomosis for Gangrene of the Leg. (Que faut-il penser de l'opération de Wieting?) F. Lejars.

66. **Arteriovenous Anastomosis for Gangrene.**—Lejars compares the arguments presented by Wieting in favor of this operation and those who denounce it as unphysiologic and dangerous. Lejars comments that Wieting, himself, says that the operation is feasible only for young and vigorous persons, without infection and when the character of the gangrene is not directly menacing. In cases such as these, Lejars remarks, a spontaneous favorable outcome is possible while there is danger that this might be compromised by the operation's inducing thrombosis. He does not definitely reject the operation but he insists that those who apply it should fully understand the dangers they thus incur. See Abstract 78 below.

69. **Treatment of Acute Suppurations in Joints.**—Dreyer found it possible to prevent suppuration in experiments on animals by injection of various powerful disinfectants after infection. Phenol. salvarsan and tincture of iodin were particularly effectual and he thinks that the latter has a promising future in this line. He tried it in a few clinical cases with eminent success. In one patient, a tuberculous girl with an acute painful affection of the knee, after injections of 3 or 5 c.c. of a 5 per cent. tincture of iodin, diluted with alcohol, the pains subsided and the lesion healed as was seen at necropsy after the patient had succumbed to miliary tuberculosis. The pains subsided at once in another case in a woman of 62 with a severe tuberculous affection of the knee requiring amputation. In a third case a boy of 16 had multiple osteomyelitis. The involvement of the knee was treated by the iodin injections and speedily healed while the other foci dragged along a tedious course. The patella was left movable and the lad is regaining the use of his knee. Dreyer thinks that these experiences with iodin justify conservative measures in treatment of arthritis more than has been possible hitherto.

70. **Movable Cecum.**—Dreyer has been studying conditions on the cadaver to determine whether movability of the cecum can be regarded as pathologic. He states that in 67 per cent. of 105 cadavers, free from any history of special intestinal trouble, he found the cecum freely movable. He further experimented to ascertain whether cecopexy produced physiologic conditions, which he found rather dubious. Among the fifty-two female cadavers the cecum was freely movable in 79 per cent. and in the few in which it was fastened, it never occupied the position in which it is placed by the routine cecopexy.

71. **Gangrene of Penis and Scrotum.**—Coenen and Przedborski summarize the details of 203 cases and add three others from their experience. In many cases the trouble was a gangrenous erysipelas. In twenty-one cases the gangrene was a secondary process and the mortality was 18.5 per cent.; in twelve cases the gangrene developed from infiltration of urine and the mortality was 8.3 per cent. It was 21.4 per cent. in twenty-eight cases in which some mechanical or chemical injury or exposure to heat or cold was responsible for the process. In the 145 cases in which the gangrene occurred in the course of a local inflammatory process, the mortality was 22.1 per cent. Good results were obtained in some cases with the actual cautery. A plastic operation afterward is seldom necessary, especially for children and even for adults as Nature restores the defect sometimes most effectually, as is shown by some of the cases cited

75. **Treatment of Prolapse of the Rectum.**—Bauer has had six children wear a celluloid corset fitting around the waist and upper part of the buttocks applying elastic spring pressure to the fold between the nates just above the anus. This lifts up the sagging pouch of Douglas which he thinks is generally responsible for the prolapse, and in a short time of wearing the corset physiologic conditions are restored and the tendency to prolapse is cured. This result was accomplished in the above six cases in from two to several weeks.

78. **Arteriovenous Anastomosis for Gangrene.**—Coenen and Wieweorowski report experiments on twenty-six dogs and on eighteen cadavers attempting to divert the blood from the femoral artery into a vein, and review thirty-four cases from the literature in which this was done, and give another case from their own experience. The end-to-side anastomosis is generally known in Germany as Wieting's operation. Their final conclusion is that it does not deserve to rank as a feasible operation as it conflicts with the anatomy and physiology of the parts. In the thirty-five clinical cases death followed in less than two days in two cases; in twelve in a few days from erysipelas, phlegmon or collapse; in one case the large intestine became gangrenous four months later and amputation had to be done later in twenty cases. In only two of the total number were the end results favorable—in Heymann's and Wieting's cases. (Wieting replies to Coenen in the last *Zentralblatt für Chirurgie* and states that he now has a record of five cases, all successful, and that these results speak louder than Coenen's more theoretical objections. (See Abstract 66 above.)

79. **End-Results of Treatment of Exophthalmic Goiter.**—Baruch reviews the ultimate outcome in ninety cases of exophthalmic goiter treated at the Breslau clinic. These are the only ones that could be followed to date of 164 cases, including eighty-two patients treated by medical measures only. The survivors include forty who had been operated on and only twenty of the eighty-two treated by medical measures alone. Marked benefit or a cure was realized in all but six of the total forty surgical survivors, while not one of the surviving medical twenty can be regarded as cured and only two as improved, while 90 per cent. show no benefit. Comparing the findings in regard to the various symptoms in the medical and surgical cases confirms still further, he thinks, the superiority of operative treatment and should compel an early operation. Hitherto the cases have not been referred to a surgeon until after failure of all internal measures, but he insists that exophthalmic goiter should be regarded as a surgical affection from the start, and that only the most desperate cases should be left in the hands of the internists. After a four-year course the outlook for benefit from any measures is poor. In 46 per cent. of the cured survivors the duration of the disease had been only six months and in 84.8 per cent. less than two years. He adds that patients with exophthalmic goiter not only belong in the surgical ward but that they should be sent there early.

81. **Transplantation of Parathyroids.**—Landois reports discouraging results from extensive experimental research in this line. Even when the transplantation proved successful and the implanted gland retained its vitality and was constantly bathed with circulating blood, yet the experience failed in every particular, showing that there is little hope for successful transplantation in the clinic of organs with an internal secretion.

82. **Laceration of Capsular Ligaments During Delivery.**—Stoltzenberg found in nine out of seventy-five cadavers of new-born infants that the capsular ligament between the atlas and axis had been lacerated. The laceration was always circular and evidently occurred by traction on the cervical region of the spine, pulling it out of the longitudinal axis. The injury is liable to be fatal from hemorrhage into the spinal canal and meninges.

84. **Hypernephroma Encroaching on the Heart.**—In the case reported by Kirschner the first disturbances were not local but were in the form of heart symptoms with great weakness, long before symptoms called attention to the urinary apparatus. Then hematuria followed and a tumor was discovered in the left kidney; it proved on removal to be a hypernephroma from aberrant suprarenal tissue proliferating into the ascending vena cava with a tumor thrombus up in the right auricle. Jumping the right ventricle it had proliferated into the pulmonary artery. The symptoms on the part of the heart had been observed for five years, a year and a half before there were disturbances in the urinary apparatus. Kirschner reviews a few similar cases of malignant thrombus formation in the literature, Winckler having had two as extensive as this in his twenty-four cases of hypernephroma. Kirschner urges others to seek for symptoms on the part of the heart with tumors of this kind.

85. **The Meiostagmin Inoculation Reaction.**—Izar recently reported that he had found that an aqueous emulsion of an ether or methyl alcohol extract of malignant tumors or pancreas, heated for an hour to 50 C. developed extremely toxic properties. If a mixture of the extract thus heated and blood-serum is centrifugated, the toxic property is concentrated in the supernatant fluid in the non-cancerous cases while it is concentrated in the sediment when the serum is derived from persons with malignant disease. The technic is the same as for the meiostagmin reaction up to the centrifugation. The sediment is mixed with salt solution and this suspension is injected into rabbits. The rabbits die within twenty-four hours when the sediment is from a cancer case, and he calls this the "meiostagmin reaction *in vivo*." He obtained positive findings in nineteen of twenty-one cancer cases and in only two of thirty-two non-malignant cases. The findings with this and the original meiostagmin reaction were constantly parallel, except that in a very few instances the *vivo* gave positive findings with known cancer when the meiostagmin reaction failed.

86. **Eye Disease in the South Sea Islands.**—Leber and Prowazek report here the results of research undertaken on a commission from the institute for marine and tropical diseases at Hamburg. They found four types of eye disease on the island of Saipan, trachoma on some of the islands and a conjunctivitis in horses, like that already described at Samoa.

88. **Cause of Acetonuria in Pregnancy.**—Porges and Novak found intense acetonuria in two diabetic women free from sugar in the urine on antidiabetic diet. This and research on some normal pregnant women has demonstrated, they state, that acetonuria in pregnancy is the result of a relative deficiency of carbohydrates in the diet. The pregnant women seem to be less able to tolerate a deficiency in carbohydrates. The data learned from pregnancy acetonuria sustain still further the assumption of impairment of liver functioning under the influence of pregnancy.

89. **Influencing of the Temperature of Children by Slight Exertion.**—Wolff found that examination of the temperature in fifty children before and after they were told to run upstairs or take some other slight exercise, showed that this exertion caused a slight rise in temperature in thirty-seven of the children. Fluctuation in the temperature after slight exertion must be regarded as a typical normal property of childhood and by no means be accepted as an evidence of tuberculosis or other latent affections. Even a ten minutes' walk or climbing a flight of stairs may send up the temperature. He concludes that the temperature findings are reliable for comparison *only* when they are taken when the children are quiet *in bed*. It is possible, he adds, that sensitive children may have their vitality depressed by this rise in temperature which may explain why certain children feel exhausted after a walk instead of refreshed by it. Conditions are better when the children are playing, as in their play, movement and rest alternate more than in a promenade.

90. **Syphilitic Heart Disease.**—Breitmann had a monograph on this subject awarded a prize twelve years ago, and he has been studying it with special care ever since, with exceptional opportunities for research as, he says, syphilis runs its most triumphant course in the small towns of Russia, reigning unmolested by treatment until the patients are driven to the physician by severe tertiary manifestations. Syphilitic affections of the heart have certain characteristic symptoms although none is pathognomonic. Gumma in the heart is seldom diagnosed, as its slow development and its predilection for the "mute" regions of the heart cause its presence to be long unsuspected unless the physician tests the functioning of the heart muscle and finds signs of weakness. But this is the explanation for many instances of sudden death in the midst of apparent health, especially in the young or middle-aged. Breitmann, Mracek and Jullien found syphilis of the heart responsible for the sudden death in from 33 to 50 per cent. of such cases, especially after physical exertion, bicycling, hydrotherapeutic measures, straining at stool or excess in drinking, etc., or slight external trauma. Even in the earliest stages of syphilis there may be symptoms on the part of the heart from disturbances in the heart muscle of anemic or toxic origin, and many supposed rheumatismal heart affections and hemiplegias are in reality of syphilitic origin. This should be suggested by the rapid onset of the heart affection with no or slight fever, with sudden weakness in the midst of apparent health; death may occur suddenly or the trouble drag along for months or years without signs of valvular mischief and without being influenced by the ordinary heart tonics. Another sign is the apparent increase in the area of dulness, without murmurs or other objective signs, while the force of the heart-beat does not increase in proportion, that is, a strong heart-beat is accompanied by only slight filling of the arteries. A progressive gummatous affection should be suspected when the heart-beat is strong but not diffuse, with a rapid pulse and tachycardia, the sounds sharp, brief and pure. If the heart beat is stronger and its area larger, but the pulse small, the gummatous affection may be referred to the left ventricle. In a recent case there was abnormal pulsation in the left ventricle, while the heart beat was absent and no heart sounds could be heard—this case represents the extreme type. Certain patients feel a slight flickering uneasiness in the chest as the extrasystole starts; others feel as if their hearts stood still during the long pause; others notice particularly the powerful beat that follows the long pause. But most patients are unaware of the irregularity from the extrasystole. A special feature of syphilitic heart disease is the disproportion between the objective findings and the actual anatomic condition; also the youth of the patients—some of his patients were only 13 when the aortic aneurysm or insufficiency or arteriosclerosis developed—also the occurrence of intermittent dyspnea and syphilitic angina pectoris. With the latter there may be an unusual passive movability of the heart, propagation of the second aortic sound to the right and upward, and involvement of other portions of the nervous and vascular systems. The one great clue is the prompt benefit from treatment as for syphilis unless irreparable conditions are already installed. The main point is to spare the heart every unnecessary exertion, and especially spare it from the effects of strong drugs. He has known of cases in which digitalis had a fatal action on a heart weakened by syphilitic disturbances in conduction or a coronary affection. The first thing is to inform the patient of

the danger in which he stands from any physical exertion. During the Adams-Stokes syndrome, the patient may derive benefit from kneeling on his knees and elbows, the Mohammedan prayer attitude; the "Karell cure" may also prove useful. Breitmann's principle, he says, is to apply "chronic," vigorous, intermittent treatment during the earliest stages of a syphilitic heart affection, but the nearer the disease to the tertiary stage, the more the gummatous tendency in the heart has led to cicatricial changes or induration, the more cautious he is in regard to any vigorous treatment or measures of any kind. This applies in particular, he adds, to salvarsan. It may be possible with salvarsan to arrest the heart affection in its early stages and ward off trouble later, but it must be borne in mind that salvarsan has a very powerful action on the heart and circulation, especially if given intravenously as is the rule now. The elasticity of the vessels is much impaired in syphilis and careful search for symptoms on the part of the heart might have revealed some which would have contra-indicated the medication in some of the cases on record in which death followed the injection of salvarsan or over-vigorous mercurial treatment.

September 16, No 13, pp. 481-528

94 *Pyelitis in Pregnancy. (Pyelitis gravidarum.) E. Venus. Commenced in No. 10.

93. **Modern Diagnostic Measures in Cancer.**—Saxl has been a pioneer in this line himself and here gives a summary of the various technics to induce a general or local reaction or utilize the natural reactions to differentiate malignant disease, explaining the scientific bases for each and the acceptance each has received from the profession. He says of the antitrypsin reaction (Brieger) that this is not strictly specific, at most in the sense that negative findings seem to exclude cancer. The meiostagmin reaction (Ascoli) seems to be giving reliable results, the findings being positive in almost every case of carcinoma and sarcoma and negative in the controls. But the technic is difficult. The cancer cell-destroying seroreaction (E. Freund) seems reliable and the technic simple except for the difficulty of obtaining the cancer cell material, as the cells of many cancers are not dissolved by normal serum, which is the basis of the test. The increase of oxyproteids in the urine in malignant disease (Salomon and Saxl) seems to be a constant phenomenon. Saxl found it in 70 per cent. of 500 cancer cases and only in five of a large number of controls. Various technics have been introduced for determining the proportion of oxyproteids, which are polypeptid bodies containing sulphur. Determination of the sulphur alone also throws light on the presence or absence of malignant disease. The technic for this is very simple: The sulphates and ethereal sulphates are removed from 150 c.c. of urine. Part of the remaining neutral sulphur is then oxidized out with dilute hydrogen dioxid and it becomes visible as a barium sulphate precipitate. Antipyrin and creosote disturb this reaction. Positive findings were obtained in 60 or 70 per cent. of the patients examined, especially pronounced with the still relatively well nourished patients, while the findings were constantly negative in 150 controls with a single exception, a moribund patient with cirrhosis of the liver. Of the reactions in the stomach content, Salomon's test has proved valuable, frequently disclosing the presence of an ulcerating gastric cancer, when all other signs had failed. A few benign ulcers give the reaction too. The technic is simple: The day before the patient eats nothing containing albumin, restricting himself to fluids. At evening the stomach is rinsed out clean and again in the morning with 400 c.c. salt solution. The rinsing fluid is filtered and tested for albumin and nitrogen. Positive findings with the Esbach test and a finding of 20 mg. of nitrogen testify to the presence of an ulcerating carcinoma. Many clinicians have published evidence in favor of the reliability of this test while three do not accept its findings, but Saxl commends the simple technic as indispensable in dubious cases. He does not think that the glycyl-tryptophan-splitting test has yet proved its right to existence, while the sources of error in the test based on the presence of a hemolytic substance in the stomach content render this test impracticable at present. In conclusion he cites without comment the latest contribution to the diagnosis of gastric cancer: Falk and Salomon's salicylate method. They give 3 gm. sodium salicylate in an enema and rinse out the fasting stomach the moment salicylic acid becomes evident in the urine. While the salicylic acid cannot be detected in the stomach fluid of the non-cancerous, with ulcerating gastric cancer, large proportions of salicylic acid are found in the stomach content; benign ulceration only very rarely permits the passage of the salicylic acid into the stomach.

94. **Pyelitis of Pregnancy.**—Venus gives a critical summary of 224 articles that have been published on pyelitis complicating pregnancy. The actual cause is not definitely established although stagnation of urine is evidently a prominent factor. Infection is generally ascending although it may be occasionally of blood-borne origin. The colon bacillus is generally responsible for it. Especial attention should be paid to a history of pyelitis in childhood. The diagnosis is usually simple but it may be necessary to exclude appendicitis, impending abortion and suppuration around the kidney. The prognosis is not absolutely favorable for the mother as complete restitution is seldom observed and there is liability to recurrence at later pregnancies, but there is no immediate danger to life. The prognosis is unfavorable for the child, as it is menaced by the tendency of the uterus to expel its contents during an attack of pyelitis and it may be necessary to interrupt the pregnancy artificially in the interest of the mother. Treatment should be conservative and expectant. Catheterization of the ureter and irrigation of the kidney pelvis are indicated in all severe cases and are often of great benefit. It is only rarely necessary to consider the question whether the pregnancy should be artificially terminated, but operative measures are required for serious degenerative processes in the kidney, such as pyonephrosis, multiple abscesses or calculi.

98. **Meningeal Symptoms with Infectious Diseases.**—Kirchheim and Schröder report two cases in which an acute or chronic suppurative meningitis was found at necropsy although there had been none of the usual symptoms of this affection

during life until the agonal phase. These cases show that the anatomic and clinical features of meningitis do *not* always correspond. They also report five cases in which nothing was found at necropsy to explain the meningitic symptoms observed during life in the course of pneumonia or scarlet fever. In two other similar cases the microscope revealed specific changes in the meninges. The meningeal symptoms are evidently the result of toxic action. The question as to whether this meningism is only the first stage of meningitis is still undecided.

103. **Colloidal Nitrogen in Urine in Malignant Disease.**—Mancini says that determination of the colloidal nitrogen in the urine is a simple and easy process, and the findings in case of malignant disease seem to be constantly characteristic. The colloidal nitrogen is that portion of nitrogen which is precipitated in the urine by absolute alcohol (Salkowski). In all morbid conditions in which colloidal substances pass into the lymph and blood in larger proportions, as during absorption of effusions and exudates, and the kidneys are working properly, the amount eliminated is unusually large in proportion. This occurs with cancer but also with pleurisy, cirrhosis of the liver, suppurative processes, etc. Mancini tabulates the findings in a number of cancer and other cases. The proportion of colloidal nitrogen to the total nitrogen is about 3.42 per cent. in normal urine and about 6.48 per cent. in cancer. If the urine at first was alkaline he rendered it slightly acid with acetic acid, and if it contained albumin, he freed it from this by boiling. The total nitrogen was determined by the Kjeldahl applied to 5 c.c. taken from the twenty-four hour urine. He then evaporated 100 c.c. from the twenty-four hour urine to 10 c.c. in the water bath, then cooled it and added 100 c.c. of absolute alcohol to precipitate the nitrogen. After standing for several hours he filtered and rinsed the filtrate with alcohol until the rinsing alcohol showed no further trace of urea. The precipitate was then dissolved in hot water and filtered and the proportion of nitrogen determined by the Kjeldahl test.

105. **Sclerosis of the Innominate Artery.**—In the two cases reported by Stadler and Albracht the symptoms suggested an aortic aneurysm but roentoscopy revealed general arteriosclerosis, most pronounced in the innominate artery which was dilated but without an actual aneurysm. They discuss the differentiation of the resulting syndrome, especially the percussion findings.

122 The Darwinian Theory. (Die Darwinsche Lehre im Umschwung der Zeiten.) G. Fritsch.

113. **Serotherapy of Epidemic Cerebrospinal Meningitis.**—Jochmann reviews the history of serotherapy of this disease and his own experience with it, the indications and results. Success depends on commencing treatment early, he says, injecting the serum into the spinal canal, with not too small doses. The treatment is aided by raising the foot of the bed for 15 to 20 cm. for twelve hours after each injection. It seemed to be borne without discomfort by the patients as a rule, but morphin had to be given in a few cases. The patients usually regained consciousness after the injection, the cerebrospinal fluid cleared up and the condition grew progressively better. In two cases, commencing optic neuritis retrogressed under the serotherapy. He is convinced that with proper dosage and wider application meningococcus serotherapy of epidemic meningitis will save many patients.

115. **Surgical Complications of Otitis Media.**—Martens discusses in particular fracture of the skull with preexisting otitis media, acute or chronic. With existing infection the mastoid process should be opened and he relates some experiences in this line, showing the advantages of surgical treatment even when infection is only menacing, but he doubts whether it is necessary in all cases of fracture of the skull. He has operated in three cases of abscess in the cerebellum with chronic otitis media. One patient succumbed to the existing meningitis and sinus thrombosis; another survived for several weeks but succumbed to progressing encephalitis. In the third case a small boy with a cerebellar abscess recovered promptly after evacuation of the abscess. In Henke's compilation of twenty-three cases of cerebellar abscess, only one of the patients survived, while seventeen survived in fifty-three cases of abscess in the temporal lobe. Martens has cured two patients on whom he operated for an epidural abscess following otitis media, as also in several cases of sinus thrombosis of this origin.

117. **By-Effects with Salvarsan.**—Galewsky has treated 370 syphilitics in the last six months with intravenous injections of salvarsan. The by-effects were always slight and transient until in a group of cases there was a succession of annoying by-effects which he finally traced to the salt solution vehicle. Since he has been paying greater care to the production of the salt solution there has been no further trouble of the kind.

118. **Salvarsan and the Eye.**—Reissert discusses this subject from the standpoint of the ophthalmologist, after summarizing the eighteen cases on record in which injury of the eye followed the injection of salvarsan in from ten days to three months. He also reports a case from his own experience in which a young man previously healthy was given a subcutaneous injection of 0.4 gm. of salvarsan a few days after the primary chancre, and eight weeks later another of 0.5 gm. of salvarsan. There were no symptoms for two months but then pain in the right side of the head and face developed and right optic neuritis and retinitis. While the other symptoms subsided under mercurial treatment, the neuritis progressed and vision was lost. Comparison of this case with those on record has convinced Reissert that the optic neuritis was due to injury from the salvarsan stored up in the tissues from the two subcutaneous injections.

141 Myonephropexy. Jacobovici and Jianu.

126. **Isolated Rupture of the Trachea.**—The rupture occurred in a boy of 9 from a contusion. The trachea was exposed at once, a cannula introduced, and removed in four days, as recovery was prompt and uncomplicated. The rapid recovery in this case should encourage immediate operation for all isolated ruptures of the trachea, as serious complications are liable to develop otherwise at any moment.

127. See Abstracts 66 and 78 above.

132. **Perforated Duodenal Ulcer in Boy of 15.** Imfeld reports a case of perforation of a duodenal ulcer in a boy of 15½, with operation at the seventeenth hour, after general peritonitis had developed. He attributes the boy's recovery in part, to the exact suture of the perforation, rinsing out of the abdomen and keeping the patient in a half-seated position. Imfeld comments on the better results with these operations in late years, the mortality having dropped since 1902 from 80 per cent. to 37.7 per cent. in Imfeld's compiled 122 cases in the last nine years. The symptoms in the case reported had been noticed for three weeks before the perforation, pain in the epigastrium coming on five or six hours after eating, until finally the perforation occurred, with intense pain above and to the right of the umbilicus, and signs of acute peritonitis followed.

138. **Local Heat in Treatment of Peritonitis.** Iselin supplements rinsing out the peritoneum in case of suppurative inflammation by applying heat continuously to the abdomen. This stimulates the vital functioning of the intestines after the abdominal operation and also aids in combating the irritation of the peritoneum without pronounced inflammation. In the latter condition it promotes absorption while after operations the effect is more physical: the augmented evaporation in the hot-air box promotes the drainage of the peritoneum, rinsing it from within outward, as he expresses it.

144 *Scoliosis Begins in Infancy. (Beginn der Skoliose.) E. Kirsch.

144. **Incipient Scoliosis.**—Kirsch insists that the tendency to scoliosis is acquired before the school age and that it should be carefully sought at all times in young children and especially those known to have rachitis. It is most readily recognized when the child lies prone on his stomach, the arms spread at right angles, the head turned first to the right and then to the left. Looking along the spine from the top and bottom, the eye on the same line as the spine or on the same plane on either side, any tendency to curvature is generally easily recognized and roentoscopy will reveal which of the vertebræ are abnormal in shape. Kirsch found curvature by this means in 5 per cent. of 196 children between 6 months and 2 years old. He urges immediate correction with a correcting bed as soon as the incipient scoliosis is discovered. Years may be necessary before normal conditions are restored. One of his patients is now 9 years old and has slept in the correcting bed since she was 2 and has lost all trace of the scoliosis although it was quite pronounced when first detected.

152 Treatment of Experimental Syphilis with Aromatic Mercury Compound. (Ueber die Behandlung der experimentellen Kaninchensyphilis mit aromatischen Quecksilbercarbonsäuren.) J. Blumenthal.

145. **Infant Physiology and Hygiene.** Opitz has had records kept of the temperature, stools, feedings and the weight in regard to 819 infants born at the Düsseldorf maternity. Of the 183 boys showing a tendency to jaundice, only 16.4 per cent. had regained their birth weight by the end of ten days, while 22.2 per cent. of the 230 free from icterus had regained it. The boys seemed to display this tendency to jaundice in much greater numbers than the girl babies and in a more intense form. His records show many interesting facts.

149. **Anesthetization of Spinal Roots for Tabetic Crises.**—König thinks that the benefits of rhizotomy may be attained in some cases of tabetic gastric crises without the necessity for an operation, merely by blocking the nerve roots involved. He urges others to try this method, and relates encouraging success with it in a single case. He used the Braun Leitungsanästhesie technic for deep paraneural injection of the anesthetic, injecting 100 c.c. of the fluid in the back, between the sixth and tenth ribs, at the emerging point of the nerves, forcing the fluid deep into the muscle on each side. He introduced the long needle close to the costovertebral articulation until it hit the rib; then it was drawn back a little, pointed upward to the upper margin of the rib and 5 c.c. of the fluid expelled at each point. The method differs from the epidural injection technic and it anesthetizes the nerve trunks for over six hours. It can be applied over and over again and if it proves possible thus to help the patients over the days of their tabetic crises in this harmless manner, much is certainly gained. It is possible, König adds, that this same paraneural technic might prove effectual for tabetic pains elsewhere, lancinating pains in the arm or leg. There is sometimes a local pain at the point of the injection, about two hours later, which he occasionally combats by subcutaneous injection of a small amount of some sedative. König's patient was a man of 44 who had severe gastric crises every month and finally every week with extreme exhaustion and loss of weight. The crises kept up for days at a time. The attack was arrested at once by deep injection of an anesthetic at the emerging points of the sixth to tenth dorsal nerve roots. 100 c.c. were injected at this time and three other attacks within the following week were likewise aborted, but not quite so successfully, possibly because not enough of the anesthetic fluid had been injected, the amounts ranging only from 65 to 80 c.c. instead of the 100 c.c. used the first time. The crises recurred after a month of peace, but the patient had left town.

162. **Influence of Neuropathic Constitution on Course of Febrile Diseases.**—Lederer gives a number of examples to show the danger of being misled by the behavior of a spoiled nervous child to assume organic nervous or brain trouble in the course of an acute febrile disease. The family physician, knowing the history of the child, is able to appreciate its vagaries at their true value, but the physician seeing the child for the first time is frequently at a loss. Treatment and care have to be strictly individualized in such cases, apathetic children roused, those with entire loss of appetite persuaded to eat or compelled to eat small amounts at brief intervals, the excited and sleepless soothed, and the children not further excited by too many therapeutic measures, packs, enemas, etc. The state of the nervous system in general should not be estimated from the behavior during an acute disease.

166. **Operative Treatment of Diffuse Peritonitis.**—Baisch reports nine cases of puerperal peritonitis from Döderlein's clinic at Munich showing the great advantages of prompt operative treatment in some of the apparently most desperate cases. He argues that there is nothing to be lost in these circumstances and everything to be gained. All the patients recovered whose infection was of endogenous origin while the four whose infection came from germs from without all succumbed. In one case nothing could be found to explain the infection from without until the woman told that finding herself bleeding profusely she had seized a scrap of soiled cotton and pushed it deep into the vagina herself. The most serious cases were always those with freshly imported septic germs. Baisch emphasizes the benefits from copious rinsing out of the abdominal cavity and free drainage. If the peritoneal cavity is already encapsulated above, drainage through the vagina is all that is necessary, but with diffuse and advanced peritonitis he provides for drainage through the vagina, the abdominal wound and both flanks, using large rubber drains. The benefit from these measures was particularly evident in a case of peritonitis following perforation during curetting of the uterus after abortion.

167. **Biologic Sugar Solution Treatment of Peritonitis.**—Kuhn analyzes the natural healing processes as the oozing out of a fluid to wash away the germs from the invaded tissues, this rinsing out process going on throughout the entire body to eliminate waste and poisons, supplemented by extensive arrangements for draining away the fluids. These facts suggest the proper aims in treatment, namely, to stimulate this oozing out of fluids, to supply plenty of fluid at other points so that the fluid will be passed along and increase the effusion at the danger points, and, further, to provide ample facilities for drainage. Kuhn then describes experimental and clinical research which has shown that a solution of sugar applied to an oozing surface has a remarkable osmotic attraction, materially enhancing the outward flow of the fluids in the tissues and thus promoting the auto-rinsing out of the peritoneum in case of peritonitic effusion. The sugar solution also answers the purpose of a rinsing fluid, and, supplemented by copious subcutaneous injection of physiologic salt solution, Nature's processes are imitated and intensified. The sugar solution attracting the fluids in the tissues outward, supplements the rinsing action of the physiologic solution injected elsewhere, while the sugar solution has the further *beneficial faculty of dissolving fibrin, thus preventing* the coagulation of fibrin and warding off the formation of adhesions and the growing together of parts. He has found that the physiologic sugar solution is a mixture of 4.1 parts grape sugar, 0.9 parts cooking salt and 100 parts distilled water. This solution does not affect the blood corpuscles nor the size of the drops in the body fluids, while it has a number of remarkable properties which adapt it for the biologic treatment of peritonitis. By stimulating the exudation it interposes a protecting sheet of fluid, constantly renewed as the fluid is drained away, and it also promotes production of antibodies and is bactericidal to a certain extent. By using a more concentrated solution, the osmotic attraction keeps up longer. Kuhn's method is to use the above sugar solution as we have been in the habit of using salt solution for rinsing the abdomen, and then toward the last he uses a more and more concentrated solution, finally leaving a certain amount of a 10 per cent. solution in the abdominal cavity.

168. **Family Infection Rather than Inherited Taint Responsible for Tuberculosis.**—Reiche reports the results of investigation of conditions in this line for 2,864 tuberculous policy holders in the Hansastädte Insurance Company. Everything tends to show, he says, the grave importance of family infection and the comparatively slight importance of inheritance in the development of tuberculosis. This dethroning of the old pessimistic theory of an inherited predisposition deprives tuberculosis of much of its horrors, as it shows how infection may be avoided and that no one is fatally doomed from birth.

172. **Retention of Placenta from Premature Administration of Ergot.**—Schmid reports a case of severe complications on account of the administration of ergot before the placenta had been expelled. He cites seven similar cases from German literature. In his case delivery had been normal; two hours later the cervix permitted passage of two fingers and there had been considerable hemorrhage, but no signs of severe anemia, no dizziness nor fainting. As there seemed to be no change in these conditions, in a few hours the physician gave ergot and sent the patient to the hospital where the cervix was found nearly closed. By this time fifty-five hours had elapsed since delivery of the child and there was a slight rise in temperature. After introduction of the inflatable bag for a few hours the placenta was evacuated by hand and the patient soon recovered.

173. **Hydrogen Dioxid a Palliative for Cancer of the Esophagus.**—Liebermeister found that when the esophagus was obstructed by a cancer and the patients were suffering from lack of food, it was possible to improve conditions for a time by having the patients sip every hour a 1 or 2 per cent. solution of hydrogen dioxid. Some of his eleven patients thus treated were restored to comparative comfort by this means and lived for months, able to take nourishment by the mouth. Of course the patients are given only food that will pass readily through the narrow passage. In case of absolute stenosis he feeds by the rectum for two or three days, during which the patients sip the dioxid solution, and then he begins with fluid food which is generally then easily passed along into the stomach. If this proves impossible, he gives a subcutaneous injection of 0.01 gm. morphin or 0.001 gm. atropin half an hour before each of the three meals.

126. **Isolated Rupture of the Trachea.**—The rupture occurred in a boy of 9 from a contusion. The trachea was exposed at once, a cannula introduced, and removed in four days, as recovery was prompt and uncomplicated. The rapid recovery in this case should encourage immediate operation for all isolated ruptures of the trachea, as serious complications are liable to develop otherwise at any moment.

127. See Abstracts 66 and 78 above.

132. **Perforated Duodenal Ulcer in Boy of 15.**—Imfeld reports a case of perforation of a duodenal ulcer in a boy of 15½, with operation at the seventeenth hour, after general peritonitis had developed. He attributes the boy's recovery in part, to the exact suture of the perforation, rinsing out of the abdomen and keeping the patient in a half-seated position. Imfeld comments on the better results with these operations in late years, the mortality having dropped since 1902 from 80 per cent. to 37.7 per cent. in Imfeld's compiled 122 cases in the last nine years. The symptoms in the case reported had been noticed for three weeks before the perforation, pain in the epigastrium coming on five or six hours after eating, until finally the perforation occurred, with intense pain above and to the right of the umbilicus, and signs of acute peritonitis followed.

138. **Local Heat in Treatment of Peritonitis.**—Iselin supplements rinsing out the peritoneum in case of suppurative inflammation by applying heat continuously to the abdomen. This stimulates the vital functioning of the intestines after the abdominal operation and also aids in combating the irritation of the peritoneum without pronounced inflammation. In the latter condition it promotes absorption while after operations the effect is more physical: the augmented evaporation in the hot-air box promotes the drainage of the peritoneum, rinsing it from within outward, as he expresses it.

162. **Influence of Neuropathic Constitution on Course of Febrile Diseases.**—Lederer gives a number of examples to show the danger of being misled by the behavior of a spoiled nervous child to assume organic nervous or brain trouble in the course of an acute febrile disease. The family physician, knowing the history of the child, is able to appreciate its vagaries at their true value, but the physician seeing the child for the first time is frequently at a loss. Treatment and care have to be strictly individualized in such cases, apathetic children roused, those with entire loss of appetite persuaded to eat or compelled to eat small amounts at brief intervals, the excited and sleepless soothed, and the children not further excited by too many therapeutic measures, packs, enemas, etc. The state of the nervous system in general should not be estimated from the behavior during an acute disease.

166. **Operative Treatment of Diffuse Peritonitis.**—Baisch reports nine cases of puerperal peritonitis from Döderlein's clinic at Munich showing the great advantages of prompt operative treatment in some of the apparently most desperate cases. He argues that there is nothing to be lost in these circumstances and everything to be gained. All the patients recovered whose infection was of endogenous origin while the four whose infection came from germs from without all succumbed. In one case nothing could be found to explain the infection from without until the woman told that finding herself bleeding profusely she had seized a scrap of soiled cotton and pushed it deep into the vagina herself. The most serious cases were always those with freshly imported septic germs. Baisch emphasizes the benefits from copious rinsing out of the abdominal cavity and free drainage. If the peritoneal cavity is already encapsulated above, drainage through the vagina is all that is necessary, but with diffuse and advanced peritonitis he provides for drainage through the vagina, the abdominal wound and both flanks, using large rubber drains. The benefit from these measures was particularly evident in a case of peritonitis following perforation during curetting of the uterus after abortion.

167. **Biologic Sugar Solution Treatment of Peritonitis.**—Kuhn analyzes the natural healing processes as the oozing out of a fluid to wash away the germs from the invaded tissues, this rinsing out process going on throughout the entire body to eliminate waste and poisons, supplemented by extensive arrangements for draining away the fluids. These facts suggest the proper aims in treatment, namely, to stimulate this oozing out of fluids, to supply plenty of fluid at other points so that the fluid will be passed along and increase the effusion at the danger points, and, further, to provide ample facilities for drainage. Kuhn then describes experimental and clinical research which has shown that a solution of sugar applied to an oozing surface has a remarkable osmotic attraction, materially enhancing the outward flow of the fluids in the tissues and thus promoting the auto-rinsing out of the peritoneum in case of peritonitic effusion. The sugar solution also answers the purpose of a rinsing fluid, and, supplemented by copious subcutaneous injection of physiologic salt solution, Nature's processes are imitated and intensified. The sugar solution attracting the fluids in the tissues outward, supplements the rinsing action of the physiologic solution injected elsewhere, while the sugar solution has the further beneficial faculty of dissolving fibrin, thus preventing the coagulation of fibrin and warding off the formation of adhesions and the growing together of parts. He has found that the physiologic sugar solution is a mixture of 4.1 parts grape sugar, 0.9 parts cooking salt and 100 parts distilled water. This solution does not affect the blood corpuscles nor the size of the drops in the body fluids, while it has a number of remarkable properties which adapt it for the biologic treatment of peritonitis. By stimulating the exudation it interposes a protecting sheet of fluid, constantly renewed as the fluid is drained away, and it also promotes production of antibodies and is bactericidal to a certain extent. By using a more concentrated solution, the osmotic attraction keeps up longer. Kuhn's method is to use the above sugar solution as we have been in the habit of using salt solution for rinsing the abdomen, and then toward the last he uses a more and more concentrated solution, finally leaving a certain amount of a 10 per cent. solution in the abdominal cavity.

168. **Family Infection Rather than Inherited Taint Responsible for Tuberculosis.**—Reiche reports the results of investigation of conditions in this line for 2,864 tuberculous policy holders in the Hansastädte Insurance Company. Everything tends to show, he says, the grave importance of family infection and the comparatively slight importance of inheritance in the development of tuberculosis. This dethroning of the old pessimistic theory of an inherited predisposition deprives tuberculosis of much of its horrors, as it shows how infection may be avoided and that no one is fatally doomed from birth.

172. **Retention of Placenta from Premature Administration of Ergot.**—Schmid reports a case of severe complications on account of the administration of ergot before the placenta had been expelled. He cites seven similar cases from German literature. In his case delivery had been normal; two hours later the cervix permitted passage of two fingers and there had been considerable hemorrhage, but no signs of severe anemia, no dizziness nor fainting. As there seemed to be no change in these conditions, in a few hours the physician gave ergot and sent the patient to the hospital where the cervix was found nearly closed. By this time fifty-five hours had elapsed since delivery of the child and there was a slight rise in temperature. After introduction of the inflatable bag for a few hours the placenta was evacuated by hand and the patient soon recovered.

173. **Hydrogen Dioxid a Palliative for Cancer of the Esophagus.**—Liebermeister found that when the esophagus was obstructed by a cancer and the patients were suffering from lack of food, it was possible to improve conditions for a time by having the patients sip every hour a 1 or 2 per cent. solution of hydrogen dioxid. Some of his eleven patients thus treated were restored to comparative comfort by this means and lived for months, able to take nourishment by the mouth. Of course the patients are given only food that will pass readily through the narrow passage. In case of absolute stenosis he feeds by the rectum for two or three days, during which the patients sip the dioxid solution, and then he begins with fluid food which is generally then easily passed along into the stomach. If this proves impossible, he gives a subcutaneous injection of 0.01 gm. morphin or 0.001 gm. atropin half an hour before each of the three meals.
